12 Abstract. In recent years, the application of compact and cost-effective deployable X-band polarimetric radars has gained in 13 popularity, particularly in regions with complex terrain. The deployable radars generally use a radome constructed by joining 14 multiple panels using metallic threads to facilitate easy transportation. As a part of the ESPOIRS project, Laboratoire de 15 l'Atmosphère et des Cyclones has acquired an X-band meteorological radar with four panel radome configuration. In this study, 16 we investigated the effect of the radome on the measured polarimetric variables, particularly differential reflectivity and differential 17 phase. Our observations reveal that the metallic threads connecting the radome panels introduce power loss at vertical polarization, 18 leading to a positive bias in the differential reflectivity values. To address the spatial variability bias observed in differential 19 reflectivity and differential phase, we have developed a novel algorithm based on the Discrete Fourier Transform. The algorithm's 20 performance was tested during an intense heavy rainfall event caused by the Batsirai cyclone on Reunion Island. The comparative 21 and joint histogram analysis demonstrates the algorithm's effectiveness in correcting the spatial bias in the polarimetric variables.

#### 25 1. INTRODUCTION

26 Doppler weather radars provide comprehensive precipitation measurements at high spatial resolution, offering valuable insights 27 into the orography-influenced precipitation processes (Georgis et al., 2000). Among different frequency bands, X-band radars have 28 gained popularity due to their compact size and affordable cost, making them well-suited for deployment in areas with challenging 29 topography. Additionally, modern polarimetric technology has dramatically enhanced the ability of X-band radars to estimate 30 precipitation, overcoming their traditional limitation of high attenuation rates in the rain (Ryzhkov et al., 1994). The ESPOIRS 31 (Etude des Systèmes Précipitants de l'Océan Indien par Radars et Satellites) project implemented by LACy (Laboratoire de 32 l'Atmosphère et des Cyclones) has utilized the advantages of X-band polarimetric radar to examine the dynamics and variability of intense tropical precipitation at the local scale, particularly its interaction with the relief of the island. Initially, an X-band radar 33 34 operating at 9.41 GHz was deployed south of Reunion Island (Figure 1a) to investigate heavy rainfall and the pronounced relief 35 effects that may contribute to rainfall intensification. Later, the radar was installed in Seychelles and Madagascar to explore 36 different geographical and meteorological contexts. The radar performed Plan Position Indicator (PPI) scans with a range gate 37 resolution of 125m and Range Height Indicator (RHI) scans with a range resolution of 25m. The radar used for this study is a 38 GAMIC GMWR-25-DP, which by design has the transceiver unit fixed just behind the antenna so that the transceiver and the 39 antenna move together and avoid the use of rotary joints.

40 Although X-band polarimetric radar offers advantages over single polarization radars, maintaining the accuracy of its polarimetric 41 data requires rigorous quality control (Park et al., 2005). One factor that can impact the performance of the radars is the radome. 42 While they play a protective role, radome can passively affect the observations due to material-related transmission losses and 43 variations in sidelobe levels (Figueras i Ventura et al., 2021; Mishra et al., 2014). Mainly, radome panels with metallic threads at 44 their joints, common in mobile radars, can introduce biases in polarimetric observations (Figueras i Ventura et al., 2021; Gourley 45 et al., 2006). The ESPOIRS X-band radar is protected by a composite radome with a 1.435m base diameter and 2m height, 46 consisting of four fiberglass-reinforced lateral segments attached through horizontally aligned metal nuts and bolts arranged along 47 the vertical axis (Figure 1b, 1c). Radar data from the Batsirai cyclone on 3 February2022 show significant biases in differential 48 reflectivity (ZDR) and differential phase (PHIDP). One of the objectives of this study is to identify the source of these biases and 49 hypothesize that they originate from the radome metal joints.

50 In similar scenarios, efforts have been made to address biases using spatial calibration curves from radar data (Figueras i Ventura 51 et al., 2021; Gourley et al., 2006). However, the stochastic nature of radar measurements introduces inherent uncertainty into 52 calibration curves, leading to an overall increase in measurement uncertainty. Previous investigations have also recommended the 53 implementation of a seamless monoblock radome to mitigate spatial bias, as it eliminates the presence of joints and, subsequently, 54 any bias. Nevertheless, the unique design of the portable ESPOIRS X-band radar, which prioritizes ease of transportation, presents 55 inherent challenges in adopting a monoblock radome solution. To address this challenge, this study proposes an adaptive Discrete 56 Fourier Transform (DFT) based algorithm to mitigate the bias. This algorithm effectively utilizes the information available in radar 57 scans and enables the correction of the ZDR and PHIDP moments for various scan strategies.

58 The distinguishing feature of this algorithm is its capacity for dynamic threshold adjustment in the correction of frequency values 59 generated by the DFT based on the characteristics of radar moments. Such adaptivity sets this algorithm apart from traditional 60 methods (Figueras i Ventura et al., 2021; Gourley et al., 2006), which employ fixed spatial calibration curves. To assess the 61 performance of the proposed algorithm, it is applied to correct the ZDR and PHIDP radar scans obtained during an intense heavy 62 rainfall event caused by the passage of the Batsirai cyclone in the vicinity of Reunion Island on February 2 to 4, 2022. The proposed method is designed to correct spatial biases in ZDR and PHIDP measurements, not absolute biases that are constant across all 63 64 azimuth directions and elevations. Correcting absolute biases that are uniform across all measurements was not the intent of our study. Section II focuses on the source of the spatial bias in ZDR, offering insights into the factor responsible for this bias. The 65 66 adaptive DFT algorithm proposed in this study is introduced in section III, providing a discussion of its mathematical formulation. 67 Section IV assesses the proposed algorithm's performance through comparative and joint histogram analysis. Section V 68 summarizes the key points of the study and outlines the direction of future research to test further and enhance the algorithm's 69 performance.

#### 70 2. SOURCE OF BIAS

To elucidate the origins of positive bias in PHIDP measurements and ascertain its underlying causes, this study employs a comprehensive approach involving the calculation of PHIDP offsets for all PPI scans conducted on the 2/3/2022 case study, 73 following the technique outlined in previous works (Figueras i Ventura et al., 2012), which utilized PHIDP offsets to discern the 74 influence of radome joints. The findings in Figure 1d exhibit a box plot distribution of PHIDP offsets across various azimuth 75 angles. Figure 1d shows a sinusoidal azimuthal pattern with four periods in the PHIDP offset. Strikingly, a distinct correlation 76 emerges between the azimuthal period positions of the PHIDP offsets and the orientation of the radome joints, with notable 77 alignment occurring at approximately 5, 85, 175 and 265 degrees. This observation strongly suggests that the metallic threads and 78 joint configuration are the key factors contributing to the bias in PHIDP. The localization of the bias near the joints is due to signal 79 phase sensitivity to path length and material properties. Radome metal joints can introduce significant phase shifts in specific 80 polarizations, impacting PHIDP measurements when signal paths intersect with these joints (Li et al., 2017), explaining the 81 observed PHIDP offset collocation with the radome joint direction.

82 The positive bias observed in ZDR can result from either an increase in horizontal reflectivity values (ZH) or a decrease in vertical 83 reflectivity values (ZV). To ascertain the cause of the positive bias in ZDR, the temporal median of horizontal and vertical 84 reflectivity obtained from RHI scan angles of 28, 300, 45 and 76 degrees on 3rd February 2022 were computed. These specific azimuth angles were selected as they were the only available RHI scans for analysis. Subsequently, for each median RHI scan at 85 28, 300, 45 and 76 degrees of azimuth respectively, elevation angles exhibiting positive ZDR bias (70, 70, 36, and 34) and unbiased 86 elevation angles (66, 67, 31, and 27) were identified for both horizontal and vertical polarization and compared as shown in Figure 87 88 2a-2d. The biased (red, blue) and unbiased (black, green) elevation angles were chosen sufficiently close to each other to ensure 89 that the same hydrometeor characteristics were observed. For example, the 34° angle marks the transition where the onset of 90 radome-induced bias becomes visible and was chosen as it is the closest elevation angle to 27° (unbiased) that still observes the 91 same precipitation pattern.

92 Figures 2a and 2b show that the horizontal reflectivity values in biased and unbiased elevation angles (red, black) exhibit a 93 consistent covariation pattern with a negligible offset. Consequently, one would expect the vertical reflectivity values (blue, green) 94 to follow a similar trend. However, it is observed that the vertical reflectivity values correlate with each other but with an offset. 95 Specifically, the biased elevation angle's vertical reflectivity (blue) has a negative offset compared to the unbiased elevation angle's 96 vertical reflectivity (green). At lower elevation angles of RHI scans, where the variance of reflectivity values across the range 97 direction is limited, a noticeable decrease in vertical reflectivity in the biased region is prominent. Specifically, at lower elevation 98 angles of the RHI scans at 45 and 76 degrees of azimuth (Figure 2c and 2d), the vertical reflectivity values in the biased region are 99 noticeably lower than their corresponding horizontal and vertical reflectivity values in the unbiased region. This indicates that the 100 metal joints have exerted a notable influence on the propagation of microwaves, particularly regarding vertical polarization. This 101 influence has led to a systematic bias in ZDR.

102 From Figures 4a and 4c, it can be noted that PHIDP and ZDR exhibit biases at somewhat different azimuth angle locations. The 103 observed bias in ZDR at varying angles, compared to the bias in PHIDP, can be attributed to distinct scattering characteristics. The 104 ZDR's azimuthal bias could arise from factors related to the scattering of incident power from the main lobe around the metallic 105 threads, which could potentially amplify the impact of the side lobes. These increased side lobe levels cause more energy to be 106 radiated or received in undesirable directions, potentially amplifying susceptibility to noise or interference from those directions 107 (Frech et al., 2013). This differs from PHIDP's bias, which is primarily influenced by the path length the radar signals traverse (Li 108 et al., 2017). Hence, the PHIDP bias are observed in the direction of the radome joints. Detailed simulations or measurements are 109 imperative for a comprehensive understanding of the precise impact of radome joints on side lobe levels, phase delays, and their 110 correlation with ZDR and PHIDP.

#### 111 **3. ADAPTIVE DFT ALGORITHM**

This study introduces a DFT algorithm to mitigate the spatial bias present in the polarimetric variables. The correction procedure starts by performing a Discrete Fourier transform on a single radar scan, which, in this case, corresponds to the 76° azimuth RHI scan measured on 02/03/2022 01:08 UTC (Figure 3a). A one-dimensional DFT is applied along the range direction to the first 100 radar gates containing rain near the radar in order to process the polarimetric variable x for a particular azimuth or elevation angle  $\theta$  and N total range gates, as shown in equation 1, where n and k represent the range gate and frequency index, respectively. The transformation F[k] is repeated for each angle  $\theta$ , respectively azimuth for PPI scans and elevation for RHI scans, systematically covering the entire radar scan to obtain F[ $\theta$ , k].

Subsequently, the power spectrum ( $P[\theta, k]$ ) is calculated from the obtained Fourier transform ( $F[\theta, k]$ ) for each azimuth/elevation angle, as depicted in Figure 3c. In Figure 3c, a three-dimensional representation is shown, illustrating the power spectrum obtained from the DFT for each elevation angle of the RHI scan. Notably, the power value of the zero frequency component ( $P[\theta, 0]$ ) derived from various elevation angles, representing the DFT's DC component, reveals three distinct peaks corresponding to the spatial bias pattern observed in Figure 3a's RHI scan. This indicates that a bias caused by the radome joints will result in a constant positive increase of the magnitude all along the range, an offset, which will show up as an increase in the power value of the DC component of the DFT spectrum.

126

$$F[\theta, k] = \sum_{n=0}^{N-1} e^{-2\pi j \frac{kn}{N}} x[\theta, n] \text{ for } 0 \le k < N$$

127 128 129

To address this bias, a correction factor (A/B) is introduced to filter the three peaks (Figure 3d) associated with the spatial bias. Notably, the correction factor is only applied to the DC component values ( $F[\theta, 0]$ ) that exceed a certain adaptive threshold.

(1)

130 131

132

$$F[\theta, 0]' = \begin{cases} F[\theta, 0] \times \frac{A}{B} & \text{if } P[\theta, 0] > \text{Median}(P[\theta, 0]) \\ F[\theta, 0] & \text{otherwise} \end{cases}$$
(2)

133

For all other frequency components  $k \neq 0$ , the values remain unchanged:

135 136

137

$$F[\theta, k]' = F[\theta, k] \quad for \ k \neq 0 \tag{3}$$

The threshold value is determined based on the moving median window of the power spectrum at the zeroth frequency (Median(P[ $\theta$ , 0]). For PPI scans, the moving median window encompasses all azimuth angles, covering a full 360 degrees. In the case of RHI scans, the window includes all available 88 elevation angles. This approach simplifies implementation by eliminating the need to define specific window sizes, which could vary with different scans or atmospheric conditions. The correction factor is calculated as the ratio between the median values of F[ $\theta$ , 0] corresponding to the power values below the threshold (A) and the median values of F[ $\theta$ , 0] corresponding to the power values above the threshold (B).

- 144
- 145  $A = Median(F[\theta, 0])|P[\theta, 0] < Median(P[\theta, 0])$ (4)

146 
$$B = Median(F[\theta, 0])|P[\theta, 0] > Median(P[\theta, 0])$$
(5)

147 
$$P[\theta, 0] = \left[\sqrt{\operatorname{Real}(F[\theta, 0])^2 + \operatorname{Img}(F[\theta, 0])^2}\right]^2$$
(6)

(7)

149 Consequently, the zeroth frequency values that surpass the threshold are multiplied by the calculated correction factor, while the 150 remaining values are left uncorrected. Figure 3d shows the power  $P[\theta, 0]$  from the DC component is characterized by distinct peaks 151 alongside the depiction of the adaptive threshold values and the reduced power after applying the correction factor. To derive the 152 corrected ZDR image (Figure 3b), an inverse Fourier transform is performed on all frequencies, encompassing the corrected DC 153 component.

154

$$x[\theta,k]' = \frac{1}{N} \sum_{k=0}^{N-1} e^{-2\pi j \frac{kn}{N}} F[\theta,k]'$$

155 156

157

### 4. ASSESSMENT OF ADAPTIVE DFT FILTERING ALGORITHM EFFICIENCY

158 The performance of the adaptive DFT filtering algorithm is assessed across different scan strategies (PPI and RHI) and different 159 polarimetric moments (ZDR and PHIDP) to determine its effectiveness. Figures 3a and 4a show increased spatial variability of 160 ZDR at specific azimuth and elevation angles of RHI and PPI scans, respectively, with a maximum variability of around 1.5-2 dB 161 observed. Similarly, Figures 4c and 5a depict increased spatial variability of PHIDP in PPI and RHI scans, with a magnitude of 162 variability around 8 to10 degrees. The application of the algorithm led to a substantial reduction in variability, as shown in Figures 163 3b, 4b, 4d and 5b. The proposed algorithm reduced the spurious ZDR variability from 1.5-2 dB to 1-1.34 dB, and the PHIDP 164 variability was reduced to less than 5 degrees. The results indicate the algorithm's effectiveness in mitigating spatial variability in both ZDR and PHIDP values across all elevation angles and scanning strategies. 165

166 The relationship between ZDR and ZH provides insights into how raindrops deviate from a perfect spherical shape. Larger 167 raindrops exhibit higher horizontal reflectivity and have their long axis oriented in the horizontal direction compared to the vertical 168 direction, thereby showing signatures of higher ZDR values. Conversely, for lower values of horizontal reflectivity (less than 30 169 dBZ), we generally expect a ZDR value of nearly zero dB due to the near spherical shape of small drops. Therefore, comparing 170 the relationship between ZH and ZDR before and after applying the algorithm (Figure 6) shows how the correction has brought 171 the biased ZDR close to the expected value. Figures 6a and 6b show the joint histogram of ZDR and ZH for all the PPI scans 172 conducted on 3 February 2022 before and after applying the correction algorithm, with the marginal distribution of ZH in the top 173 and the marginal distribution of ZDR on the right side. Likewise, figures 6c and 6d show the joint histogram of ZDR and ZH for all the RHI scans on the same date, before and after applying the correction algorithm. Figures 6a and 6b encompass data from all 174 175 PPI scans covering various azimuth angles and distances, whereas Figures 6c and 6d are specific to the RHIs for the four azimuth 176 angles chosen in Figure 2. This distinction accounts for the differences between Figures 6a and 6c (and likewise, Figures 6b and 177 6d). As these figures capture the data before any attenuation correction, the reflectivity distribution ranges from light drizzle (near 178 zero dBZ) to heavy rainfall ( $\cong$ 40 dBZ). It can be observed from Figure 6a, 6c that the distribution of ZDR extends significantly 179 beyond 2dB for reflectivity values below 30 dBZ. Such increases arise from the spatial positive bias in ZDR discussed in view of 180 Figures 3a and 4a. The impact of the developed algorithm on the distribution of ZDR is highlighted in Figures 6b and 6d. Following 181 the correction, the mean distribution of ZDR shifts towards values closer to zero, approaching the theoretical values at lower 182 reflectivity. Furthermore, the correction also results in a noticeable increase in negative values of ZDR, indicating the presence of 183 differential attenuation fingerprints, a common occurrence in X-band radar systems, which were not as discernible before the 184 correction. Figures 6b and 6d reveal the impact of the algorithm in successfully addressing the positive bias in ZDR.

#### 185 5. CONCLUSION

186 This study investigates the impact of radome joints on the polarimetric variables of a portable X-band weather radar. The radome 187 design introduces spatially dependent biases in polarimetric variables due to preferential loss of power in vertical polarization 188 caused by metallic thread alignment. Due to the stochastic nature of radar measurements, these spatial errors exhibit variability 189 across different scans. This study proposes a novel adaptive DFT algorithm to address the changing bias. The algorithm is 190 formulated with the understanding that the bias caused by the radome joints remains constant along the range. Consequently, the 191 DFT applied along the range exhibits an increase in magnitude in the zeroth frequency component (DC) for azimuth angles aligned 192 with the radome joint positions compared to those misaligned. This leads to varying offset values of polarimetric variables across 193 azimuths and elevations depending on the radar beam position with respect to radome joint positions. The algorithm detects and

194 reduces the spatial bias pattern by suppressing the increase in offset values.

The algorithm's performance in mitigating the positive spatial bias in ZDR and PHIDP is evaluated by applying the algorithm in the PPI and RHI polarimetric variable scans measured during the Batsirai cyclone event on 3 February 2022. The results show that

- 197 the adaptive DFT algorithm presented herein effectively addresses the spatial biases, enhancing the accuracy of ZDR and PHIDP
- 198 measurements regardless of the scan type.

As the primary source of spatial bias originates from vertical polarization, the algorithm's effectiveness is further validated by examining the relationship between ZH and ZDR values. Notably, the correction reduces the positive bias observed in ZDR at lower reflectivity levels, bringing the mean ZDR value closer to the expected levels. Additionally, the algorithm reveals negative

- 202 ZDR values, indicating the presence of attenuation fingerprints.
- 203 The proposed algorithm has limitations related to sample size and precipitation type. To effectively distinguish between 204 meteorological targets and bias, it requires a large, noise-free sample along the range direction. Additionally, its performance relies 205 on suppressing variations in the magnitude of the DC component of DFT observed across continuous azimuth angles. As a result, 206 the algorithm performs optimally in scenarios characterized by uniform precipitation, such as stratiform precipitation and large 207 convective systems that cover extensive areas around the radar. However, for isolated or scattered precipitation systems located in 208 limited range and azimuth gates, the algorithm's performance needs to improve due to its inability to capture variations in the DC 209 component magnitude derived from the DFT. To advance future research and potential improvements, an area of interest lies in 210 evaluating the proposed algorithm's performance by conducting measurements both with and without the radome. An additional 211 consideration is the possibility of incorporating a seamless monoblock radome as a future plan.
