15 **Abstract.** The OCO-2 and GOSAT series of satellites provide near-global coverage of CO<sub>2</sub> and CH<sub>4</sub> mixing ratios. To  
16 accurately derive emission fluxes from the observed mixing ratios, it is crucial that these data meet specific precision  
17 and systematic error requirements. In this study, we report validation results for GOSAT and OCO-2 over South Asia,  
18 obtained using a portable Fourier Transform infrared Spectrometer (FTS) at a tropical rural site (Gadanki; Latitude:  
19 13.45° N, Longitude: 79.18° E) in Southern India, from November 2015 to July 2016. Biases in CH<sub>4</sub> mixing ratios from  
20 GOSAT ranged from -9 to -18.5 ppb, depending on the collocation criteria, while CO<sub>2</sub> data from OCO-2 demonstrated  
21 better accuracy and precision, meeting the requirements of ESA's Climate Change Initiative (CCI). Using the  
22 FLEXPART model, we also show that CH<sub>4</sub> emissions from regional sources accounted for only 35% of the day-to-day  
23 observed variability. Both model-derived and observed mixing ratios exhibited the same seasonal variation, with higher  
24 values in October–November and lower values in June–July. However, the observed mixing ratios decreased by approx-  
25 imately 100 ppb, while the model-derived values decreased by only 20 ppb, suggesting that atmospheric chemistry and  
26 variations in background concentrations play a significant role over South India.

## 27 1 Introduction

28 Carbon dioxide (CO<sub>2</sub>) and methane (CH<sub>4</sub>) are the two top most important greenhouse gases (GHGs) responsible for  
29 anthropogenic global warming. While the role of CH<sub>4</sub> in global warming is of primary interest, CH<sub>4</sub> also plays an im-  
30 portant role in atmospheric chemistry by affecting OH amount, ozone production in remote areas and water (produc-  
31 tion) in the stratosphere (Fiore et al., 2002; Fleming et al., 2015; Laughner et al., 2021; Noel et al., 2018). Both CO<sub>2</sub> and  
32 CH<sub>4</sub> abundances in the atmosphere are on continuous rise post-industrial era (Dunn et al., 2022; Turner et al., 2022) and  
33 hence a continuous global monitoring of carbon dioxide and methane is highly desirable for identifying sources, sinks,  
34 trends and effective implementation of global treaties on reduction of greenhouse gases by individual countries. Satel-  
35 lites due to their continuous improving data products, have come to be recognized as important tool in recent decade for  
36 monitoring and studying greenhouse gases. Satellites such as GOSAT and OCO-2 capture scattered solar radiation in  
37 the near infrared spectral region and provide columnar mixing ratios. GOSAT and OCO-2 are providing global cover-  
38 age every 3 days and 15 days respectively (Table 1).

39 **Table 1. Launch date, equator crossing time, revisit time for global coverage and sensor technology of satellites, the data of**  
 40 **which are used in the study.**

Name of satellite/sensor	Agency responsible for launch / maintenance	Launch Date	Equator crossing time	Satellite revisit time on same location	Greenhouse Gas related Data products	Principle of measurement
GOSAT aka Ibuki	JAXA, Japan / NIES, Japan	23 January 2009	13:00	3 days	Columnar CO <sub>2</sub> Columnar CH <sub>4</sub> CO <sub>2</sub> profile CH <sub>4</sub> profile	Fourier Transform Spectrometer
OCO-2 (Orbiting Carbon Observatory - 2)	JPL, USA	July 2014	13:35	16 days	Columnar CO <sub>2</sub>	Diffraction grating

41 Satellite based estimates of greenhouse and trace gases have proved effective for deriving the emission fluxes (Bergamaschi et al., 2007, 2009; Bousquet et al., 2010; Chevallier et al., 2005). However, the improvement that can be  
 42 achieved in emission fluxes depends highly on the accuracy of satellite retrievals. Climate Change Initiative (CCI) programme of European Space Agency (ESA) has listed the threshold precision and systematic error requirements for satellite  
 43 derived columnar CO<sub>2</sub> and CH<sub>4</sub> mixing ratios (henceforth, columnar mixing ratios of CO<sub>2</sub> and CH<sub>4</sub> are represented  
 44 by symbols XCO<sub>2</sub> and XCH<sub>4</sub> respectively), which are < 8 ppm precision and < 0.5 ppm systematic error for XCO<sub>2</sub> individual  
 45 measurements, and < 34 ppb precision and < 10 ppb systematic error for XCH<sub>4</sub> individual measurements for  
 46 deriving the regional emission fluxes of these species (Chevallier et al., 2016). WMO's Global Climate Observing System (GCOS) implementation plan has listed 1-sigma accuracy requirement of < 0.5 ppm for XCO<sub>2</sub> and < 5 ppb for  
 47 XCH<sub>4</sub>, respectively (GCOS-200, 2016).

51 To validate satellite-based estimates, standards against which the satellite observations can be compared are needed.  
 52 The Total Carbon Column Observing Network (TCCON) operates high-resolution ground-based Fourier transform infrared spectrometers (FTS) for providing column-averaged greenhouse gas abundances with high accuracy and precision.  
 53 TCCON observations serve as the reference data source for satellite validation. Recently, TCCON is supplemented by portable FTS operated in the framework of the Collaborative Carbon Column Observing Network (COCCON).  
 54 TCCON currently operates more than 20 stations worldwide for high precision measurements of column average dry air mole fractions of CO<sub>2</sub>, CH<sub>4</sub>, N<sub>2</sub>O, HF, CO, H<sub>2</sub>O and HDO (<https://tcccon-wiki.caltech.edu>; accessed in Sep 2024). All  
 55 the sites follow common set of standards for instrumentation, data acquisition, calibration and analysis as prescribed by the TCCON Steering committee. TCCON sites use IFS 125HR FTS manufactured by Bruker Optics which cover a  
 56 spectral range from 3900 cm<sup>-1</sup> to 15500 cm<sup>-1</sup> with a spectral resolution of 0.02 cm<sup>-1</sup>. The calibration of TCCON is  
 57 achieved using aircraft profiling over the sites. Typical error in XCO<sub>2</sub> is less than 0.2% for solar zenith angle less than  
 58 83° (Wunch et al., 2011a). While the XCO<sub>2</sub> and XCH<sub>4</sub> measured at TCCON sites are highly accurate and very important for validation of satellite, model and other instruments, the spectrometer is expensive, large and requires continuous  
 59 maintenance. The IFS 125HR FTS dimensions are of the order of 1 m x 1 m x 3 m and weighs several 100 kg,  
 60 restricting its wide spread use or its deployment for short field campaigns or at remote sites with limited manpower. To  
 61 supplement TCCON observations and to provide wider coverage of GHG observations, the Karlsruhe Institute of Technology (KIT) in collaboration with Bruker Optics, started developing a new type of portable FTS in 2011 which pro-  
 62  
 63  
 64  
 65  
 66  
 67

68 vides accurate measurement of GHGs while being lightweight and cost-effective. The prototype performance is de-  
69 scribed in Gisi et al. (2012). The spectrometer has become commercially available since 2014 under model designation  
70 EM27/SUN. Sha et al. (2020) compared the four different types of low-resolution spectrometers against IFS 125HR as  
71 well as in-situ observations using AirCore from one of the TCCON site over a period of 8 months and found  
72 EM27/SUN had the best performance matrix against high resolution spectrometer. COCCON is an emerging network of  
73 the portable FTS which uses tested and calibrated EM27/SUN spectrometers as well as common algorithms for data  
74 processing (Alberti et al., 2022; Frey et al., 2019; Sha et al., 2020). Support for calibration and data processing is pro-  
75 vided by KIT and the COCCON spectrometers are calibrated against TCCON by performing side-by-side observations.  
76 Today, more than 83 EM27/SUN spectrometers are operated worldwide under COCCON network (Alberti et al.,  
77 2022a). The portability of EM27/SUN spectrometer and high accuracy in retrieving XCO<sub>2</sub> and XCH<sub>4</sub> have made the  
78 instrument and COCCON network being used in a variety of applications. Pak et al. (2023) and Herkommer et al.  
79 (2024) have used EM27/SUN spectrometer as travelling standard to evaluate consistency of TCCON measurements.  
80 Frausto-Vicencio et al. (2023) have used EM27/SUN spectrometer to estimate combustion efficiency of wild fires at  
81 regional scale. Stremme et al. (2023) have used the spectrometer to study CO<sub>2</sub> plumes from volcano. Dietrich et al.  
82 (2021) and Alberti et al. (2022b) have used them for detecting city scale gradient in the gas mixing ratios and identify-  
83 ing the sources of emissions.

84 An assessment conducted by Buchwitz et al. (2017) using TCCON sites found that GOSAT and OCO-2 meet the re-  
85 quirements set by ESA's CCI Programme and WMO's GCOS implementation plan across various parts of the world.  
86 However, due to a lack of data, this systematic assessment has so far not been conducted over South Asia. However,  
87 there have been a few studies that compared satellite data with ground-based FTIR observations from Shadnagar  
88 (17°05' N, 78°13' E), near Hyderabad, Telangana—a city in the south-central part of India. Sagar et al. (2022) com-  
89 pared XCH<sub>4</sub> values from Sentinel-5P/TROPOMI (from December 2021 to March 2021) with ground-based FTIR ob-  
90 servations and found a mean bias of 3.61 ppb. Pathakoti et al. (2024) compared XCO<sub>2</sub> data from the OCO-2 satellite  
91 with ground-based FTIR and reported a mean bias of 3.81 ppm and a root mean square error (RMSE) of 6.6 ppm.  
92 Pathakoti et al. (2024) used version 8 bias-corrected OCO-2 data. Aside from these few studies, no systematic ground  
93 validation of satellite data for GHGs has been conducted over the South Asian region. Additionally, there has been no  
94 validation of GOSAT over South Asia. Since the release of version 8 of OCO-2 data, several improvements have been  
95 made to the OCO-2 algorithm, and the latest version (v11.1) is now available to public users.

96 National Atmospheric Research Laboratory (NARL), Gadanki and Institute for Meteorology and Climate Research  
97 (IMK-ASF) of Karlsruhe Institute of Technology (KIT), Karlsruhe collaborated to make XCO<sub>2</sub> and XCH<sub>4</sub> measure-  
98 ments over South India using a portable Fourier Transform Spectrometer (FTS) similar to the one in COCCON net-  
99 work. In this manuscript, we present a systematic validation of XCO<sub>2</sub> and XCH<sub>4</sub> estimated from GOSAT and OCO-2  
100 over a site in South Asia using ground-based measurements and using the latest retrieval algorithms.

## 101 2 Instrumentation and Data

102 In this study, a commercial low resolution (0.5 cm<sup>-1</sup>) FTS (Model: EM27/SUN FTS Make Bruker) with modified sun-  
103 tracker and InGaAs detector is used. The spectrometer has high thermal and mechanical stability and 0.5 cm<sup>-1</sup> spectral  
104 resolution in the spectral range 5000 to 9000 cm<sup>-1</sup>. KIT has developed a sun-tracker system that utilizes image of sun on  
105 field stop of spectrometer to guide sun-tracker for accurate position of the sun. This allows far more precise sun-  
106 tracking even when intensity over the sun disk is varying due to cloud or other factors. The tracking accuracy achieved  
107 is of the order of 11 arc sec (Gisi et al., 2011). A detailed description of the instrument can be found in Gisi et al.

108 (2012). The instrument used has been calibrated by performing side-by-side measurements next to the TCCON spec-  
109 trometer in Karlsruhe. The instrument is calibrated for specific deviations from nominal instrumental line shape (ILS)  
110 and the absence of any other systematic errors is verified at KIT. Details about the ILS measurement and data analysis  
111 as well as the comparison of calibration factors between the COCCON spectrometers have been discussed in Frey et al.  
112 (2019), Sha et al. (2020) and Alberti et al., (2022). Sha et al. (2020) have found a mean bias of  $-0.18 \pm 0.45$  ppm and  
113  $0.003 \pm 0.005$  ppm between EM27/SUN and TCCON instrument for XCO<sub>2</sub> and XCH<sub>4</sub> respectively. Ratios of XCO<sub>2</sub> and  
114 XCH<sub>4</sub> values estimated using the instrument unit is used in current study (Instrument Sr. No. 52) and the reference IFS  
115 125HR had values of 0.999482 and 1.000825 before the start of the observations at Gadanki (Alberti et al., 2020). In  
116 addition to solar spectra, measurements of atmospheric parameters like temperature and pressure were also obtained  
117 near the spectrometer.

## 118 2.1 Ground-based FTS

119 The recorded spectra are analysed using retrieval code PROFFAST v2.4 developed at KIT (KIT IMK-ASF 2024a).  
120 PROFFAST software retrieves the gas amount by fitting solar absorption spectra and scaling the a priori atmospheric  
121 profiles of the gases. It was run using a python interface PROFFASTpylot v1.3 which also takes care of preprocessing  
122 of raw instrument data (Feld et al., 2024; KIT IMK-ASF 2024b). PROFFAST algorithm is validated in several studies  
123 and used across all the COCCON sites to provide uniform and consistent data processing (Frey et al., 2019; Gisi et al.,  
124 2012; Hase et al., 2004; Sepúlveda et al., 2012; Sha et al., 2020). The spectral windows used for different species are  
125 shown in Table 2. The algorithm requires vertical profiles of temperature and pressure and a priori estimates of profiles  
126 of species to be estimated. Vertical profiles of temperature and pressure are obtained from NCEP reanalysis data corre-  
127 sponding to the dates of observations. The a priori estimates of species profiles are obtained from WACCM (Whole  
128 Atmosphere Community Climate Model) (Marsh et al., 2013) which is the average of 40 year monthly mean values for  
129 the site. The preprocessing step involves quality check of interferogram, DC correction, fast fourier transform, phase  
130 correction and resampling of the spectra. Each record of raw data is a set of 10 spectra of which 5 are captured when the  
131 mirror is moving forward and 5 are captured when the mirror is moving backward. The interferogram is checked for  
132 signal level and source brightness fluctuations also known as DC variability and is removed from further analysis if  
133 threshold levels are not met. The other measurement and instrument specific corrections included in the processing are  
134 DC correction (correction for the sun brightness fluctuations) (Keppel-Aleks et al., 2007) and the application of instru-  
135 mental line shape (ILS) parameters (Abrams et al., 1994; Alberti et al., 2020; Hase et al., 1999; Messerschmidt et al.,  
136 2010). As the first step, the columnar concentrations of CO<sub>2</sub>, CH<sub>4</sub>, O<sub>2</sub> and H<sub>2</sub>O in terms of number of molecules per m<sup>2</sup>  
137 are retrieved. Then, the CO<sub>2</sub> and CH<sub>4</sub> concentrations are converted to column average mixing ratios by assuming O<sub>2</sub>  
138 mixing ratio as 20.95% and normalising CO<sub>2</sub> and CH<sub>4</sub> concentrations with respect to O<sub>2</sub>. This allows for compensating  
139 various systematic errors. XCO<sub>2</sub> measurement precision is 0.13 ppmv and XCH<sub>4</sub> measurement precision is 0.6 ppbv  
140 (Frey et al., 2019).

141 Table 2. List of spectral windows used for retrieving columnar concentrations of various gases using ground-based FTS

Species	Spectral windows used for analysis
CH <sub>4</sub>	5897 – 6145 cm <sup>-1</sup>
CO <sub>2</sub>	6173 – 6390 cm <sup>-1</sup>
O <sub>2</sub>	7765 – 8005 cm <sup>-1</sup>
H <sub>2</sub> O	8353.4 – 8463.1 cm <sup>-1</sup>

142 Observations were carried out from October 2015 to July 2016 in the Gadanki campus of NARL. Gadanki (Latitude:  
143 13.45° N, Longitude: 79.18° E, 360 m above mean sea level) is a rural site in South India with a tropical wet climate. It  
144 experiences two monsoon seasons known as southwest and northeast monsoon seasons. Change in wind circulation  
145 from one season to the other season is known to have significant effect on trace-gases and aerosol concentrations at the  
146 site (Renuka et al., 2014; 2020; Suman et al., 2014). The site is surrounded by hilly terrain and the nearest city is about  
147 35 km away. A major part of the terrain surrounding Gadanki is forest and farm lands. Though there is no farming of  
148 rice (paddy field) in the immediate vicinity, the region as a whole has a good number of paddy fields. More details  
149 about the site and various atmospheric observation facility can be found in Pandit et al. (2015) and Jayaraman et al.  
150 (2010). The FTS observations were carried out from morning to evening at an interval of 1 minute except during days  
151 with inclement weather and weekends. More than 39,000 spectra covering a period of 10 months were analysed to re-  
152 trieve XCO<sub>2</sub> and XCH<sub>4</sub>.

## 153 2.2 GOSAT

154 The greenhouse gases observing satellite (GOSAT) also known as IBUKI is a joint project of the Ministry of the Envi-  
155 ronment (MoE), Japan; the National Institute for Environmental Studies (NIES), Japan and the Japan Aerospace Explo-  
156 ration Agency (JAXA), Japan (Yokota et al., 2009). The main instrument onboard GOSAT is a Thermal and Near infra-  
157 red Sensor for carbon Observations (TANSO) (Table 1). It is a Fourier transform spectrometer (FTS) with two detec-  
158 tors, one for shortwave infrared (SWIR) wavelength range and the other for thermal infrared (TIR) wavelength range  
159 (Olsen et al., 2017). While the TIR sensor is used to retrieve CO<sub>2</sub> and CH<sub>4</sub> profiles, the SWIR sensor is used to retrieve  
160 column average dry mole fraction of CO<sub>2</sub> (XCO<sub>2</sub>) and CH<sub>4</sub> (XCH<sub>4</sub>). In the current study, only XCO<sub>2</sub> and XCH<sub>4</sub> values  
161 from SWIR sensor are used. The retrieval of XCO<sub>2</sub> is a four-step process involving pre-processing, data screening, re-  
162 trieval and quality check. The pre-processing involves correction for observation time, pointing anomalies, wave-  
163 number, sensor degradation, etc., and preparing meteorological data. In the second step, data are screened out for the  
164 presence of cloud, high solar zenith angle (> 70°), high ground surface roughness, elevated aerosol layer, etc., along  
165 with 13 instrument related quality flags. XCO<sub>2</sub> and XCH<sub>4</sub> values are then retrieved by minimizing difference between  
166 observed and simulated spectra. The Goddard Earth Science Data Information and Services Center of National Aero-  
167 nautics and Space Administration (NASA), USA provides XCO<sub>2</sub> data retrieved from GOSAT satellite's SWIR sensor  
168 under Atmospheric CO<sub>2</sub> Observations from Space (ACOS) project (Osterman et al., 2017). In this study, FTS SWIR L2  
169 v3.05 XCO<sub>2</sub> and XCH<sub>4</sub> bias corrected data products from National Institute for Environmental Studies (NIES), Japan  
170 and ACOS Level 2 bias-corrected XCO<sub>2</sub> version v9.2 full physics retrieval data from Goddard Earth Sciences Data and  
171 Information Services Center are used.

## 172 2.3 OCO-2

173 Orbiting Carbon Observatory-2 (OCO-2) is NASA's Earth remote sensing satellite to study atmospheric carbon dioxide  
174 from space (Crisp et al., 2004). In the current work, we have used processed and bias corrected data version 11.1r  
175 downloaded from the website of Goddard Earth Science Data Information and Services Center (GES DISC;  
176 <http://disc.gsfc.nasa.gov/>). Version 11.1r is the latest version of data which were released in May 2023. The version  
177 11.1r data contains retrospectively retrieved XCO<sub>2</sub> values using full physics algorithm with several improvements with  
178 respect to its predecessor algorithms (Payne et al., 2023). The OCO-2 was launched on July 2, 2014 in sun-synchronous  
179 orbit with equatorial crossing time at 13:30 on an ascending node with 16 days repeat cycle (Table 1). OCO-2 instru-  
180 ment consists of three boresight high resolution imaging grating spectrometers which provides high resolution spectra  
181 of reflected sun light in oxygen A band (0.765 μm) and in two CO<sub>2</sub> bands at 1.61 and 2.06 μm. The instruments can be

182 operated in three modes viz., target, glint and nadir. The ground resolution varies depending on the mode of operation.  
183 In the current study, data from the nadir mode are used which has the spatial resolution of 1.29 km x 2.25 km (Crisp et  
184 al., 2017). The spectra are corrected for various artefacts such as bad pixels, cosmic ray artefacts and converted to radi-  
185 ometric values. Using full physics radiative transfer model, synthetic spectra are produced and compared with observed  
186 spectra. An inverse model iteratively modifies the assumed atmospheric state to improve the fit. The number densities  
187 of CO<sub>2</sub> and O<sub>2</sub> thus retrieved are used to get XCO<sub>2</sub> by taking ratio of them and multiplying it by 0.2095. The retrieval is  
188 further applied bias correction obtained from collocated TCCON data (O'Dell et al., 2018). More details of the retrieval  
189 process are available in Crisp et al. (2021). The OCO-2 data are distributed in two formats known as standard files and  
190 Lite files. The standard files contain CO<sub>2</sub> mixing-ratios without bias correction whereas mixing-ratios in the Lite files  
191 are bias corrected (Payne et al., 2023). The data files contain quality flag for each retrieval. The quality flag value “0”  
192 corresponds to good data, whereas the quality flag value “1” suggests the presence of any of the 24 algorithmically  
193 identified quality issues in the retrieved value. In the present work, we have used bias corrected data with quality flag  
194 “0” only.

### 195 3 FLEXPART (A Lagrangian Particle Dispersion Model)

196 Besides, comparing satellite data with ground-based observations, we have also examined the seasonal variation of me-  
197 thane mixing ratios using a Lagrangian Particle Dispersion Model to understand the influence of local sources vis-a-vis  
198 long-range transport. The FLEXPART (Pisso et al., 2019), an open source model developed at NILU is widely used by  
199 the research community around the world to identify the source regions of long range transport. The model takes mete-  
200 orological fields as input and tracks the movement of virtual particle forward or backward in time. The particle can be  
201 configured to represent a gas or aerosols of one's choice and accordingly be subjected to various physical processes  
202 such as advection, turbulence, dry deposition, wet deposition, radioactive decay, etc. Except for reaction with OH radi-  
203 cal no other chemical transformation is modelled in FLEXPART.

204 We configured FLEXPART for backward-in-time run from observation site (Gadanki) with virtual particle representing  
205 methane molecules. The backward-in-time runs provide a source-receptor relationship which can be used to calculate  
206 mixing ratios or concentrations at observation site using emission fluxes. The model run is configured such that mixing  
207 ratios thus calculated represent results of emissions within the past 10 days and average of 0 to 15 km atmospheric col-  
208 umn at the observation site. This configuration effectively captures most regional emissions and tropospheric methane  
209 mixing ratios. Using few sensitivity tests we have found that emissions within 10 to 15 days have insignificant contribu-  
210 tion to concentrations beyond 15 km. More details of the model settings used for the current study are provided in Table  
211 3.

212 **Table 3. The FLEXPART model setup and the input data details**

Input Meteorological Data	ECMWF Reanalysis – Interim (ERA-Interim) (Dee et al., 2011)
Tracer	CH <sub>4</sub>
Point of origins for retroplume (aka Release Point)	Gadanki Latitude: 13.45° N Longitude: 79.18° E, Site altitude: 365 m a. s. l. Plume release altitudes from ground: 0 – 15 km.

Number of particles released for each day	100000
Mode	Backward runs
Number of days backward for each release	10 days
User selectable Processes	Dry Deposition – disabled Convection – enabled Wet deposition – disabled Reaction with OH radical – enabled
OH reaction related settings	Constants $C = 9.65 \times 10^{-20} \text{ cm}^3 \text{ molecule}^{-1} \text{ sec}^{-1}$ $D = 1082.0 \text{ K}$ $N = 2.58 \text{ (no unit)}$

### 213 3.1 ECLIPSEv6 inventory

214 In order to calculate the concentrations resulting from recent regional emissions (emissions within past 10 days of a  
215 given observation), we used ECLIPSEv6b (Evaluating the CLimate and air quality ImPacts of Short-livEd pollutants  
216 version 6b) emission inventory (Amann et al., 2011, 2012; Klimont et al., 2017; Hoglund-Isaksson, 2012; Stohl et al.,  
217 2015). The inventory is prepared following IPCC (2008) recommended method and using GAINS model (Amann et al.,  
218 2011) for 11 species including CH<sub>4</sub> across 8 economic sectors. The data are provided as 0.5° x 0.5° gridded values for  
219 the years from 1990 to 2050 at an interval of 5 years for two scenarios namely current legislation for air pollution,  
220 which is also the reference scenario and maximum technically feasible reductions scenario. The latest version (version  
221 6b) was released in August 2019 and incorporates updates for historical data, new waste sectors, soil NO<sub>x</sub> emissions,  
222 international shipping emissions and energy-macroeconomic data. The inventory includes only anthropogenic emission  
223 fluxes from sectors viz. energy, industry, solvent use, transport, domestic combustion, agriculture, open biomass and  
224 agricultural waste burning, and waste treatment. Natural emissions from wetlands, forest fires, biogenic emissions, etc.  
225 are not included in the inventory. The total Global, South Asia (members of SAARC – South Asian Association for  
226 Regional Cooperation), and India’s emissions of methane for the year 2015 were 336.2, 44.2 and 31.5 Tg, respectively.

### 227 3.2 Wetland Inventory

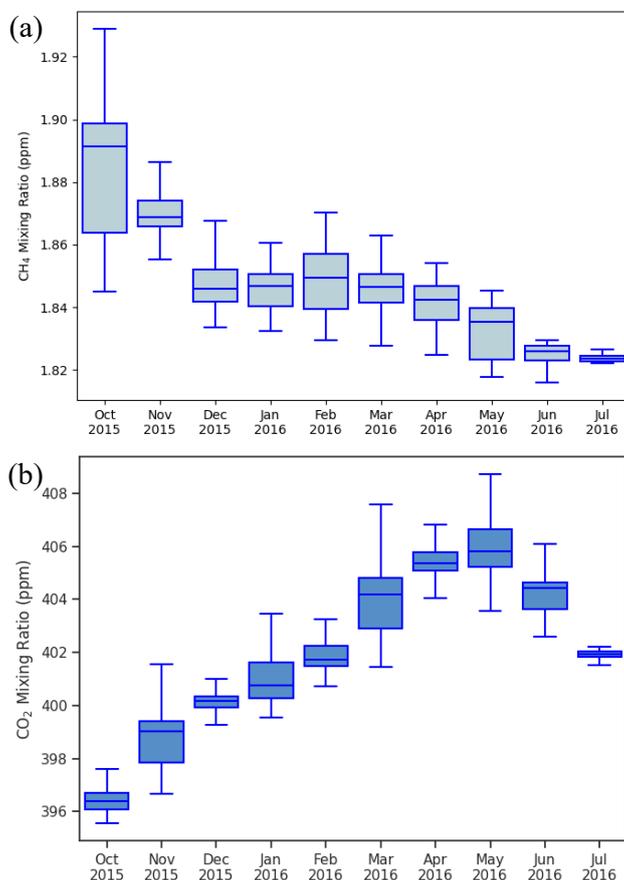

228 The emissions from wetlands can contribute significant atmospheric load of methane at the observation site and hence  
229 in addition to anthropogenic emissions from ECLIPSEv6 inventory, we used WetCHARTs version 1.0 inventory  
230 (Bloom et al., 2017a, b) for calculating methane concentrations at Gadanki from recent emissions. The inventory con-  
231 tains global monthly emission fluxes of methane at 0.5° by 0.5° resolution for ensemble of multiple terrestrial biosphere  
232 models, wetland extent scenarios and temperature dependencies. The emission fluxes from 2001-2015 are provided for  
233 three choices of global scaling, two choices of wetland spatial extent, two choices for temporal variability of wetland  
234 extent, nine choices of heterotrophic respiration schemes and three choices of parametrization scheme for temperature  
235 dependency. In the current work, we have used data corresponding to the scaling factor with global emissions 166  
236 TgCH<sub>4</sub> yr<sup>-1</sup>, CARDAMOM (CARbon DAta MOdel fraMework) terrestrial C cycle analysis for heterotrophic respira-  
237 tion (Bloom et al., 2016), mid-range temperature sensitivity and, spatial and temporal extent of wetlands constrained  
238 with SWAMPS (Surface WATER Microwave Product Series) multi-satellite surface water product (Schroeder et al.,  
239 2015). These choices are made based on following consideration. Choice of scaling factor represents the mid-point  
240 global emissions among the three choices available viz. 124.5, 166 and 207.5 Tg CH<sub>4</sub>/yr. While there are nine choices  
241 for heterotrophic respiration, there is only one choice available for emission fluxes after 2010 which is CARDAMOM  
242 and used here. Between the two choices of spatial extent and two choices of temporal variability, the SWAMP multi-

243 satellite surface water product is used because it represents observationally constrained inundated areas including lakes  
244 and other water bodies.

#### 245 4 Results and Discussion

246 Box plots of monthly statistics are shown in Figure 1 for (a) XCH<sub>4</sub> and (b) XCO<sub>2</sub> measured by EM27/SUN at the  
247 Gadanki site. Figure 2 shows the time series of hourly mean values of XCH<sub>4</sub> and XCO<sub>2</sub> from EM27/SUN, OCO-2,  
248 ACOS and GOSAT within box size  $\pm 30^\circ$  longitude and  $\pm 10^\circ$  latitude of the site (Table 4). A large variability in XCH<sub>4</sub>  
249 values is observed in October, but in other months, the variability is relatively low. The median values of XCH<sub>4</sub> are  
250 found to systematically decrease from 1.892 ppm in October to 1.826 ppm in June of the following year, with similar  
251 values observed in July. The monthly median values of XCO<sub>2</sub> increased from 396.4 ppm in October to 405.8 ppm in  
252 May, then began to decrease after May. Unlike XCH<sub>4</sub>, the XCO<sub>2</sub> values did not show high variability in October. A  
253 similar seasonal variation was observed by Jain et al., (2021) in surface mixing ratios of CO<sub>2</sub> and CH<sub>4</sub> at Gadanki. Ka-  
254 vitha and Nair (2016) using SCIAMACHY satellite data over India for the period 2003-2009, also reported similar sea-  
255 sonal variations, attributing them to regional rice cultivation patterns. Further discussion on the seasonal variation is  
256 provided in the subsequent section.

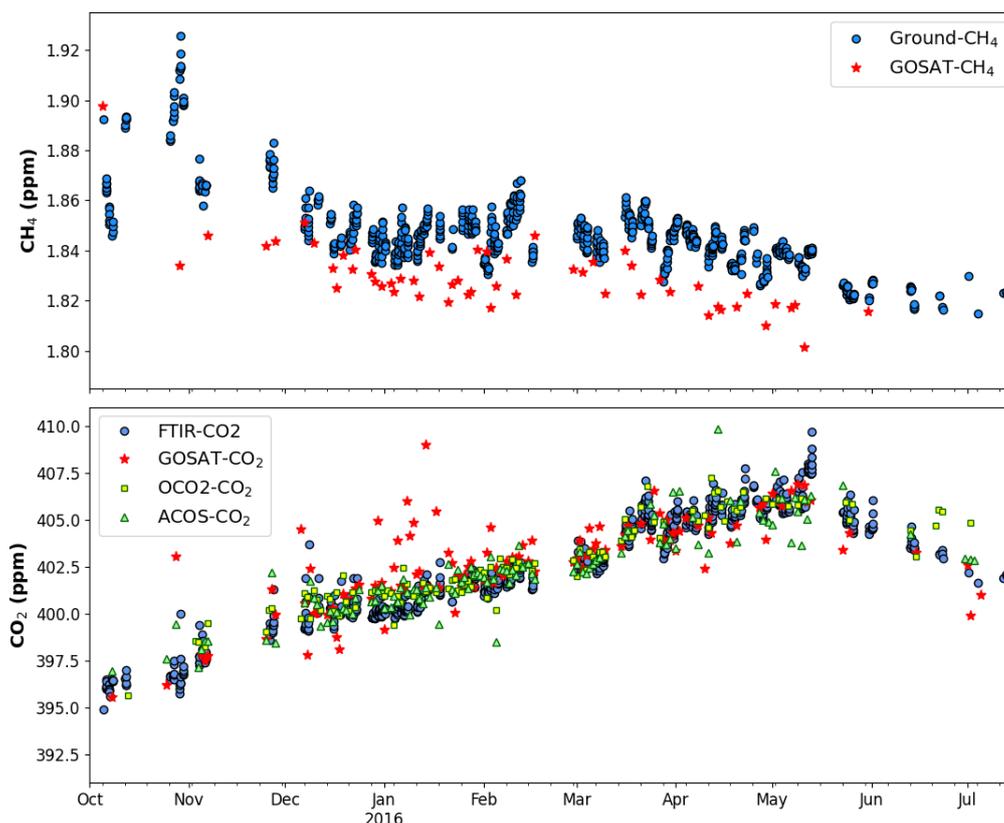

257

261 **Figure 2. Hourly mean values of columnar CH<sub>4</sub> (top) and CO<sub>2</sub> (bottom) mixing ratios observed using ground based FTIR**  
262 **along with paired satellite observations. See the text for description of pairing method (GOSAT data version 3.05; OCO-2**  
263 **data version v11.1r; ACOS v9.2; Box size ±30° longitude and ±10° latitude)**

#### 264 4.1 Comparison of satellite-based and ground-based mixing-ratios

265 The GOSAT satellite observes the same point on Earth every three days, and gas retrievals are performed only under  
266 clear sky conditions. This limits the number of concurrent observations available with ground-based FTIR. To over-  
267 come this limitation and ensure sufficient number of paired ground and satellite data for comparison, we have followed  
268 an approach similar to Buchwitz et al. (2017). This approach relies on the fact that CO<sub>2</sub> and CH<sub>4</sub> have long atmospheric  
269 residence times, allowing the history of air parcels to be used to pair data for comparison.

270 In this approach, the first step is to identify all satellite data within a certain distance of the ground station. Buchwitz et  
271 al. (2017) used satellite data within ±30° longitude and ±10° latitude of TCCON sites to evaluate GOSAT and OCO-2  
272 data products. Wunch et al. (2017) used box of ±5° longitude and ±2.5° latitude around the TCCON sites in the North-  
273 ern Hemisphere and ±60° longitude and ±10° latitude around the TCCON sites in the Southern Hemisphere to evaluate  
274 XCO<sub>2</sub> estimates from the OCO-2 satellite. In the second step, ground-based observations within three days of the satel-  
275 lite overpass and within two hours of the same time of day are paired with the satellite data. In the third step, the data  
276 pairs obtained in step 2 are further filtered using the criterion that the CAMS model output of XCH<sub>4</sub> and XCO<sub>2</sub> values,  
277 interpolated to the satellite location and ground station, cannot differ by more than 0.25 ppm for XCO<sub>2</sub> and 5 ppb for  
278 XCH<sub>4</sub>, respectively. This third step is based on the premise that the CAMS model is capable of simulating transport  
279 accurately, meaning that while the absolute values may not always be correct, the spatial variability in the model is reli-

280 able. The criteria in step 3 ensures that satellite and ground values are only compared when they share the same air mass  
 281 history. It should be noted that the absolute value of the model simulation and its differences with observations are not  
 282 relevant in this step. More detailed discussions on the need and the rationale behind this complex approach for data  
 283 pairing can be found in Nguyen et al. (2014) and Wunch et al. (2011b).

284 We performed calculations for three different box sizes around the observation site at Gadanki (13.45° N, 79.18° E):  
 285 ( $\pm 5^\circ$  longitude,  $\pm 2.5^\circ$  latitude), ( $\pm 10^\circ$  longitude,  $\pm 5^\circ$  latitude), and ( $\pm 30^\circ$  longitude,  $\pm 10^\circ$  latitude). By the end of the  
 286 third step, we obtained 55 pairs of XCH<sub>4</sub> from GOSAT v3.05, 117 pairs of XCO<sub>2</sub> from GOSAT v3.05, 118 pairs of  
 287 XCO<sub>2</sub> from ACOS v9.2 and 120 pairs of XCO<sub>2</sub> from OCO-2 v11.1 for the biggest box-size in Step 1 (see Table 4, Fig-  
 288 ure 2). The number of data pairs for XCO<sub>2</sub> is more than double that of XCH<sub>4</sub> for all box-sizes. This difference reflects  
 289 the fact that carbon dioxide has a much longer atmospheric lifetime (>100 years) compared to methane (~12 years).

290 **Table 4: Mean bias and scatter between satellite and ground-based measurements.**

Satellite	Species	Product version	Box Size for pairing		Number of data points	Bias = mean (X <sub>sat</sub> - X <sub>grd</sub> )*	Scatter = stddev(X <sub>sat</sub> - X <sub>grd</sub> )*	Pearson correlation coefficient R
			Longitude	Latitude				
GOSAT	XCH <sub>4</sub>	v3.05	$\pm 30$	$\pm 10$	55	-18.5 ppb	13.8 ppb	0.47
			$\pm 10$	$\pm 5$	19	-9.07 ppb	12.1 ppb	0.75
			$\pm 5$	$\pm 2.5$	12	-12.8 ppb	6.21 ppb	0.85
	XCO <sub>2</sub>	v3.05	$\pm 30$	$\pm 10$	117	0.644 ppm	1.69 ppm	0.74
			$\pm 10$	$\pm 5$	59	0.812 ppm	1.88 ppm	0.59
			$\pm 5$	$\pm 2.5$	27	0.983 ppm	1.59 ppm	0.67
		ACOS v9.2	$\pm 30$	$\pm 10$	118	0.163 ppm	1.09 ppm	0.90
			$\pm 10$	$\pm 5$	54	0.077 ppm	1.25 ppm	0.86
			$\pm 5$	$\pm 2.5$	38	-0.212 ppm	1.02 ppm	0.90

\*X<sub>sat</sub> are satellite based mixing ratio estimates and X<sub>grd</sub> are ground based FTIR mixing ratio estimates. For all the satellites, their bias corrected values are used.

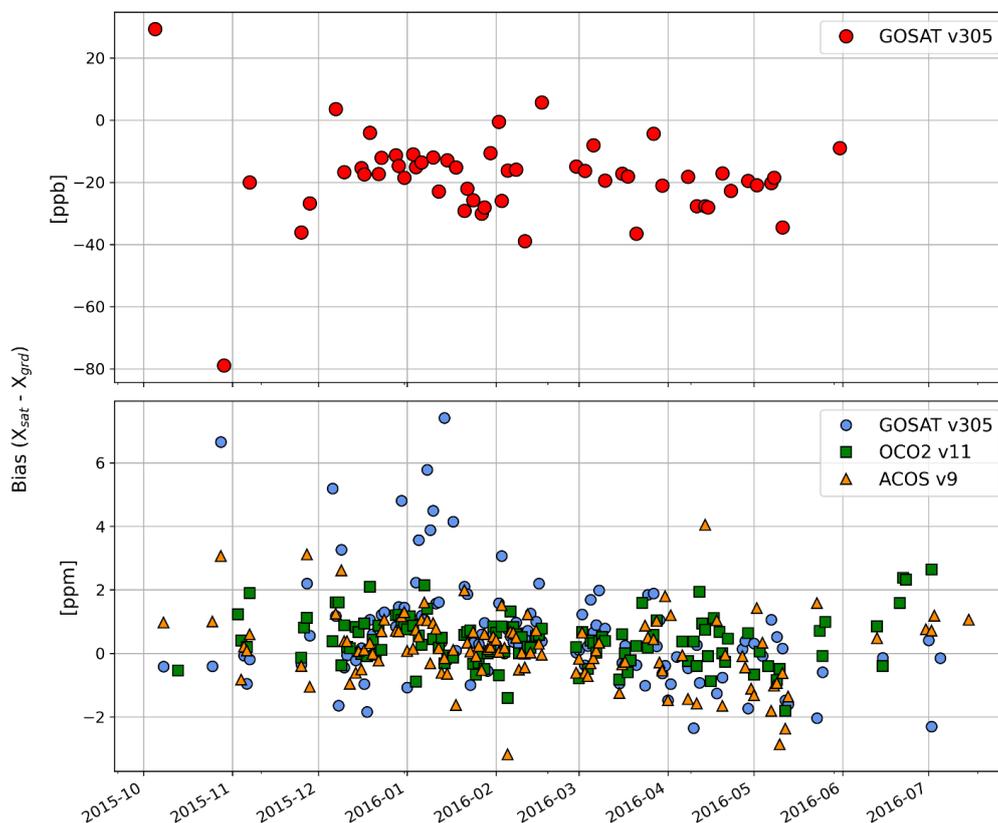

291 With the dataset in place, we now assess the bias, scatter, and correlation between satellite and ground-based measure-  
 292 ments in Table 4. The bias is defined as the mean of difference between the satellite and the ground-based mixing ratio,  
 293 the scatter is defined as the standard deviation of the differences, and the correlation coefficient between ground and  
 294 satellite data is the Pearson correlation coefficient. The Climate Change Initiative (CCI) of ESA has specified precision  
 295 (scatter) and systematic error (bias) requirements of < 34 ppb and < 10 ppb for XCH<sub>4</sub> (Chevallier et al., 2016). Statisti-  
 296 cally significant correlation exists between ground-based and satellite measurements for all box sizes (Table 4).

297 The bias in GOSATv3.05 XCH<sub>4</sub> data is -9.07 ppb for the 20° x 10° longitude-latitude box size, meeting the CCI re-  
 298 quirement, though it was larger for the other box sizes. The scatter requirement of < 34 ppb is met with a significant  
 299 margin for all box sizes. The scatter ranged from 6.2 ppb to 13.8 ppb from the smallest to the largest box size.

300 The correlation between GOSAT XCO<sub>2</sub> and ground-based XCO<sub>2</sub> is significant for all the box sizes used for data pair-  
 301 ing. The Climate Change Initiative (CCI) of ESA has specified precision (scatter) and systematic error (bias) require-  
 302 ments of < 8 ppm and < 0.5 ppm for XCO<sub>2</sub> (Chevallier et al., 2016). The bias is lowest, at 0.644 ppm, for the largest

303 box size ( $60^\circ$  long x  $20^\circ$  lat) and highest, at 0.983 ppm, for the smallest box size ( $10^\circ$  long x  $5^\circ$  lat). The larger box sizes  
304 correspond to the criteria set by Buchwitz et al. (2017), while the smaller box sizes correspond to Wunch et al. (2017).  
305 Neither meets the CCI listed systematic error (bias) requirements of  $< 0.5$  ppm. However, the scatter requirement of  $< 8$   
306 ppm is comfortably met. The scatter values for GOSATv3.05  $XCO_2$  are in the range of 1.59 ppm to 1.88 ppm.  
307 ACOS version 9.2  $XCO_2$  values, which are derived from the GOSAT satellite but use a different algorithm, perform  
308 significantly better than the GOSATv3.05 values. Bias values range from -0.212 ppm to 0.163 ppm, and scatter values  
309 range from 1.02 ppm to 1.25 ppm, depending on the longitude-latitude box size. The correlation for ACOS values is  
310 also far superior. The correlation coefficient values for ACOS v9.2  $XCO_2$  are between 0.86 and 0.9, whereas the corre-  
311 lation coefficient values for GOSAT v3.05  $XCO_2$  range from 0.59 to 0.74.  
312 The correlation of ground data with OCO-2  $XCO_2$  is the highest among the three satellite  $XCO_2$  datasets evaluated. The  
313 correlation coefficients (R values) for OCO-2  $XCO_2$  v11.1r are between 0.94 and 0.95. The biases also meet the CCI  
314 requirement of  $< 0.5$  ppm, though they are slightly larger than those for ACOS  $XCO_2$ . The biases for OCO-2  $XCO_2$   
315 range from 0.163 ppm to 0.408 ppm for different longitude-latitude boxes. The scatter for OCO-2 ranges from 0.776  
316 ppm to 0.806 ppm, depending on box size, and is significantly smaller than both the GOSAT  $XCO_2$  v3.05 and ACOS  
317  $XCO_2$  v9.2 values, meeting the CCI criteria of  $< 8$  ppm.  
318 Figure 3 shows the time series of biases for  $XCH_4$  and  $XCO_2$  using a  $\pm 30^\circ \times \pm 10^\circ$  longitude-latitude box around  
319 Gadanki. No systematic changes in biases are observed for both  $XCH_4$  and  $XCO_2$ . The biases at the Gadanki location  
320 are consistent with those ( $\sim 1$  ppm) reported by O' Dell et al. (2018) for OCO-2 version 8 data over TCCON sites.

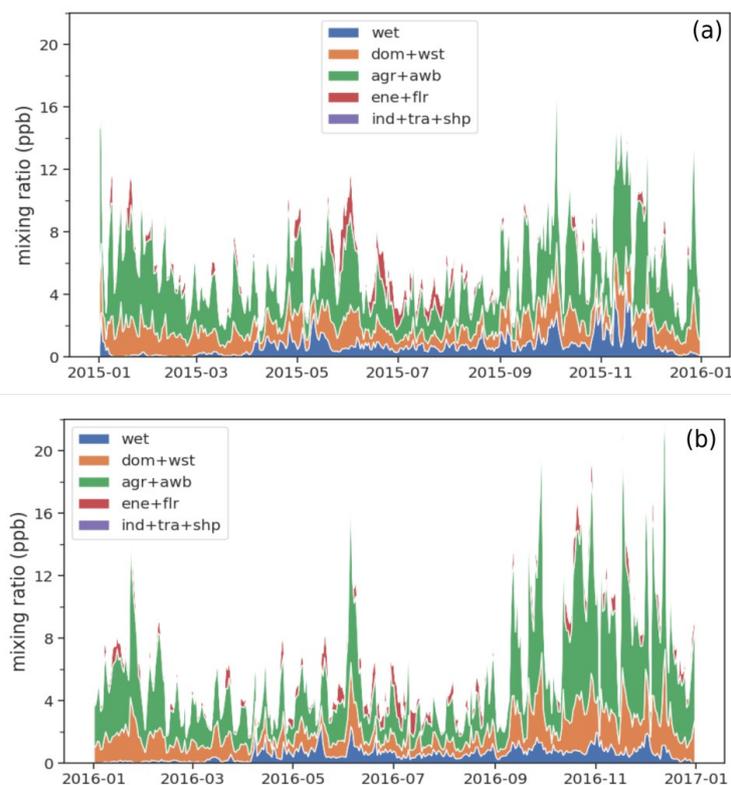

321 **Figure 3:** Time series for biases in GOSAT and OCO-2 estimated  $XCH_4$  (top) and  $XCO_2$  (bottom) values over Gadanki, In-  
322 dia. Values are shown for  $\pm 30^\circ$  longitude and  $\pm 10^\circ$  latitude box around the station.

#### 323 4.2 Case Studies and Seasonal variations

324 **Figure 4** shows methane mixing ratio enhancements calculated using the FLEXPART model and the  
325 ECLIPSEv6+Wetland inventory. As previously mentioned, the model is configured such that the values represent day-  
326 time mean mixing-ratios in the altitude range of 0 to 15 km over Gadanki, contributed by emissions from the preceding  
327 10 days. The altitude range of 0 to 15 km is selected because the tropopause altitude in the tropics is typically between  
328 15 and 18 km (Pandit et al., 2014), and emissions from the past 10 days are generally confined within this range.  
329 The 10-day back trajectory is chosen based on earlier work by Gadhavi et al. (2015), which demonstrated that, for the  
330 Gadanki location, a 10-day back trajectory captures emissions from almost the entire South Asia. The averaging period  
331 is selected as daytime (9 am to 6 pm local time) to ensure a one-to-one correspondence with observed mixing ratios,  
332 which are measured using solar radiation through FTS and are therefore only available during daylight hours.  
333 Hereafter, these values will be referred to as model values. However, it is important to note that the model values do not  
334 account for the columnar CH<sub>4</sub> mixing ratio resulting from emissions prior to the 10-day period and, therefore, do not  
335 represent the total columnar mixing ratio as seen in FTS or satellite data.

336

337 **Figure 4:** Model calculated columnar (0 to 15km) average methane mixing ratio enhancements due to emissions of past 10  
338 days for year (a) 2015 and (b) 2016. Colours show contribution of different sectors viz. wetland (wet), domestic+waste  
339 (dom+wst), agriculture + agricultural waste burning (agr+awb), energy + flaring (ene+flr), and industry + transport + ship-  
340 ping (ind+tra+shp).

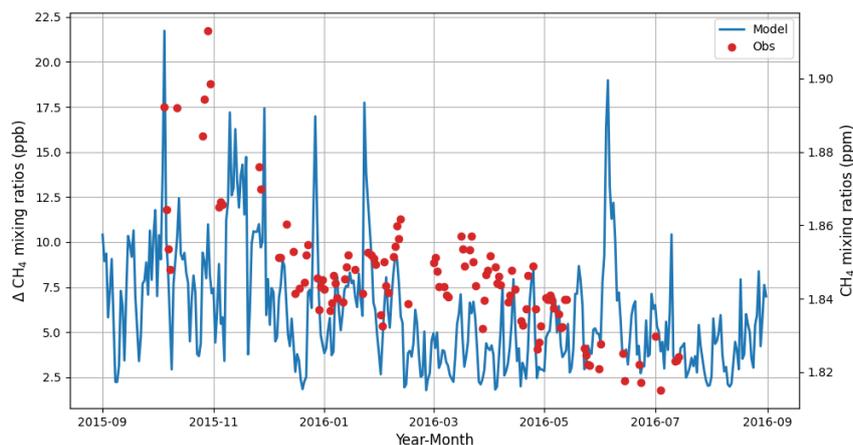

341 Overall, the model estimates methane mixing ratio enhancements ranging from 2 ppb to 26 ppb during 2015 and 2016.  
342 While there is significant day-to-day variability, a seasonal pattern is still discernible in the model-calculated values.  
343 Typically, the mixing ratio enhancements are high in November, decreases slightly in December, and rise again during

344 January and February. They decrease in March and April, briefly rise in the second half of May, and then decrease  
345 again, remaining low from June to September. The mixing ratios rise again in October, peaking in November. Sector-  
346 wise, wetlands do not show large seasonal variations. Wetland contributions are low from December to March. In other  
347 seasons, wetland contributions occasionally reach as high as 40% of total mixing ratios, but for most part of the year,  
348 they remain around 10%. The highest contribution comes from the agriculture sector, accounting for nearly 55% of the  
349 total mixing ratio enhancements, followed by the waste sector, which contributes about 17% to the model values at  
350 Gadanki. The domestic and energy sectors contribute about 5% each. The domestic sector's contribution is lower in  
351 July and August, mainly due to the air masses originating from the west of Gadanki in peninsular India, where the  
352 population is smaller and contributes less to methane emissions. Flaring contributes negligibly for most part of the year,  
353 but during June to July, its contribution can reach up to 40%, primarily due to low emissions from other sectors during  
354 this period and the winds from the Arabian Sea bringing emissions from oil rigs off the west coast of India, the eastern  
355 Arabian Peninsula, and northeastern Africa. Industry, transport, shipping and agricultural waste burning activities con-  
356 tribute less than 1% of atmospheric load of methane at Gadanki.

357 **Figure 5** shows model-calculated methane mixing ratio ( $\Delta XCH_4$ ; solid blue line; left Y-axis) and the methane mixing  
358 ratios ( $XCH_4$ ) observed using FTS (red filled circles; right Y-axis) in a single plot. The left Y-axis represents the model  
359 mixing ratio, which only accounts for emissions from the preceding 10 days. For lack of a better term, we refer to it as  
360  $\Delta XCH_4$ . The right Y-axis shows the observed values in ppm. As mentioned earlier, the model was configured to reflect  
361 incremental variability caused by regional emissions. If the background  $CH_4$  mixing ratios were constant, the day-to-  
362 day variability relative to background values should be the same in both the model and the observations. However, we  
363 observe differences in both the absolute values of variability and their seasonal patterns. Several sudden increases in the  
364 model values, which appear as spikes in **Figure 5** (e.g. 5 October 2015 and 27 December 2015), correspond to increase  
365 or decrease in the observations. While the observations are not as continuous as model values and cannot capture all the  
366 variability seen in the model, some degree of day-to-day variability is correlated between the model and observations  
367 ( $R^2 = 0.35$ ). However, the magnitude of variability between the model and observed values is quite different. For in-  
368 stance, the observed mixing ratios from 5 October 2015 to 8 October 2015 decreased by 49 ppb, whereas the model  
369 values during the same period decreased only by 16 ppb. Over the entire observation period, observed values varied by  
370 100 ppb, while the model values varied only by 20 ppb. This discrepancy may be due to two main factors: either the  
371 emission fluxes in the emission inventory are underestimated, or the background mixing ratios are not constant. The  
372 latter factor could explain the mismatch on a monthly scale. Starting in October 2015, both model and observed values  
373 are high and decrease toward June-July 2016. While the model values are already low by March 2016, the observed  
374 values decrease gradually from November 2015 to January 2016, remain nearly constant from January 2016 to April  
375 2016, and then decrease rapidly in May, reaching a minimum during the last week of June and the first week of July.

376 Chandra et al. (2017) analysed methane variations over different parts of India using JAMSTEC's Atmospheric Chemi-  
377 cal Transport Model. They found that, over South India, although 60% of the columnar concentration is attributed to  
378  $CH_4$  in the lower troposphere, there is very little correlation between regional emissions and columnar methane varia-  
379 tions. This was attributed to changes in atmospheric chemistry and transport. According to Chandra et al. (2017), the  
380 methane loss rate increases from 6 ppb day<sup>-1</sup> in January to 12 ppb day<sup>-1</sup> from April to September. Additionally, anticy-  
381 clonic winds in the upper troposphere confine uplifted methane molecules over broader South Asia during the monsoon  
382 season, contributing significantly to methane over Western India, but not significantly over South India. Since the  
383 FLEXPART doesn't include chemistry other than the reaction with OH radical, lower decrease in model values from  
384 March to July could be due to absence of chemistry as well as transport of background methane above 15 km.

385

## 388 5 Conclusions and Outlook

389 The GOSAT and OCO-2 satellites provide global coverage of columnar mixing ratios of CO<sub>2</sub> and CH<sub>4</sub> every 3 and 15  
390 days, respectively. These data are crucial for deriving regional greenhouse gas emission fluxes. However, the accuracy  
391 of the derived emission fluxes strongly depends on the precision and accuracy of the satellite products. In our study, we  
392 compared GOSAT and OCO-2 satellite-measured columnar mixing ratios of CO<sub>2</sub> and CH<sub>4</sub> with ground-based FTS  
393 measurements from a location in South India.

394 The biases in methane mixing ratios estimated using the GOSAT satellite ranged from -9 ppb to -18.5 ppb, depending  
395 on the matching criteria used for the collocation of ground and satellite footprints. These biases meet ESA's CCI re-  
396 quirement for systematic errors (< 10 ppb) for the smallest longitude-latitude box size. However, the bias is marginally  
397 higher than the acceptable limit for the middle box-size and does not meet the requirement for the largest box size ( $\pm 30^\circ$   
398 longitude  $\times$   $\pm 10^\circ$  latitude) used for matching ground and satellite pairs.

399 The biases in carbon dioxide mixing ratios were lowest for the ACOS v9.2 dataset among the three datasets evaluated.  
400 Both the ACOS and OCO-2 data meet ESA's CCI requirement for CO<sub>2</sub> biases (< 0.5 ppm), while the GOSAT v3.05  
401 values showed higher biases, ranging from 0.644 ppm to 0.983 ppm. The precision requirement of < 8 ppm for XCO<sub>2</sub>  
402 set by ESA CCI was met by all three datasets with a significant margin, with scatter values ranging from 0.776 ppm to  
403 1.88 ppm.

404 Our study demonstrates that satellite-based greenhouse gas estimates over South Asia show promising accuracy and  
405 precision for emission flux retrievals. In recent years, several new satellites from both public and private organizations  
406 have been launched to provide greenhouse gas estimates. This highlights the need for sustained efforts to establish a  
407 wider and denser network of Fourier Transform Spectrometer (FTS) across South Asia, which can be used for satellite  
408 and model validations with implication for better assessment of GHGs emissions and improved climate modelling.

409 **Code availability**

410 PROFFAST Code used to retrieve columnar concentration of GHGs from raw interferograms is publicly available. The  
411 link is provided in the main text as well as in acknowledgement section. Source code of FLEXPART model is publicly  
412 available. The link for FLEXPART is provided in the main text and in the acknowledgement section.

413 **Data availability**

414 Satellite data are publicly available and their links are provided in main text as well as in acknowledgement. Data of  
415 ground-based Fourier transform spectrometer will be made available through institute's website or through public re-  
416 pository soon. Currently, they can be obtained by writing email to HG.

417 **Author contribution**

418 HG, AJ, and FH conceptualised the study. HG, CJ, MS and MF did data curation. HG carried out formal analysis. HG  
419 and AA carried out model runs and analysis of model output. HG prepared visualization and wrote original draft. SR,  
420 CJ, AJ and FH reviewed and edited the draft.

421 **Competing interests**

422 One of the authors is a member of the editorial board of journal Atmospheric Measurement and Techniques.

423 **Acknowledgements**

424 Authors gratefully acknowledges following dataset and software providers and their funding agencies. Physical Re-
