**Abstract.** Particulate nitrate is a major component of ambient aerosol around the world, present in inorganic form mainly as ammonium nitrate, and also as organic nitrate. It is of increasing importance to monitor ambient particulate nitrate, a reservoir of urban nitrogen oxides that can be transported downwind and harm ecosystems. The unit-mass-resolution time-of-flight aerosol chemical speciation monitoring equipped with capture vaporizer (CV-UMR-ToF-ACSM) is designed to quantitatively monitor ambient  $\text{PM}_{2.5}$  composition. In this paper, we describe a method for separating the organic and ammonium nitrate components measured by CV-UMR-ToF-ACSM based on evaluating the  $\text{NO}_2^+/\text{NO}^+$  ratio ( $\text{NO}_x^+$  ratio). This method includes modifying the ACSM fragmentation table, time averaging, and data filtering. By using the measured  $\text{NO}_x^+$  ratio of  $\text{NH}_4\text{NO}_3$  and a plausible range of  $\text{NO}_x^+$  ratio for organic nitrate aerosol, the measured particulate nitrate can be split into inorganic and organic fractions. Time averaging and data filtering results in a concentration limit of  $0.6 \mu\text{g m}^{-3}$  total particulate nitrate, above which this method could be used. We show that this method is able to distinguish periods with inorganic or organic nitrate as major components at a rural site in the Netherlands. A comparison to a high-resolution time-of-flight aerosol mass spectrometer equipped with a standard vaporizer (SV-HR-ToF-AMS) shows a good correlation of particulate organic nitrate fraction between the instruments ( $\text{CV/SV} = 1.59$ ;  $r^2 = 0.92$ ). We propose that researchers use this  $\text{NO}_x^+$  ratio method for CV-UMR-ToF-ACSM to quantify the particulate organic nitrate fraction at existing monitoring sites in order to improve understanding of nitrate formation and speciation.

## 1 Introduction

In the current age of decreasing sulfur emissions, nitrate is becoming a principal aerosol component globally and regionally (Adams et al., 1999; Metzger, 2002; Liao et al., 2003; Rodriguez and Dabdub, 2004; Feng and Penner, 2007; Bauer et al., 2007; Paulot et al., 2016; Bian et al., 2017; Vasilakos et al., 2018; Drugé et al., 2019; Lu et al., 2021). In addition to an increasing  
20 aerosol fraction of ammonium nitrate ( $\text{NH}_4\text{NO}_3$ ), ambient organic nitrates (ON) produced through the oxidation of volatile organic compounds (VOCs) in the presence of nitrogen oxides ( $\text{NO}_x$ ) can condense into the particulate phase or grow new particles (Huang et al., 2019a, b; Song et al., 2024). The particulate ON (pON) contribution to total particulate nitrate mass ( $\text{pNO}_3$ ) is substantial (Ng et al., 2017), with an average fraction of 17%-31% in China (Yu et al., 2024), 34%-44% in Europe (Kiendler-Scharr et al., 2016), and large differences between urban and rural areas (Fisher et al., 2016; Schlag et al., 2016;  
25 Romer Present et al., 2020; Yu et al., 2024). Improved understanding of pON fraction in different regions can provide insight into chemical mechanisms of secondary aerosol formation (Pye et al., 2015; Lee et al., 2016; Ng et al., 2017; Zare et al., 2018).

ON flux worldwide accounts  $\sim 25\%$  of the total nitrogen deposition (Jickells et al., 2013). Zare et al. (2018) estimated, via WRF-Chem simulations in the southeast United States, that 60% of  $\text{NO}_x$  loss is related to ON chemistry. Similar to inorganic nitrate, ON also can be regarded as a  $\text{NO}_x$  reservoir, because thermal or photolysis processes can re-release  $\text{NO}_x$ .  
30 The partitioning between the gas-phase and particulate ON (Zare et al., 2018) can affect this reservoir lifetime, and thus the spatial scale of transport of urban nitrogen emissions from their source, determining how far downwind these emissions can harm natural habitats (Fields, 2004; Bobbink and Hicks, 2014; Erisman et al., 2015; Melillo, 2021).

The  $\text{NO}_x^+$  ratio method, first described by Farmer et al. (2010), is a robust method to separate the total  $\text{pNO}_3$  signal measured by high resolution-aerosol mass spectrometers (AMS) into particulate ammonium nitrate (pAmN) and particulate organic  
35 nitrate (pON) using the variation of  $\text{NO}_2^+/\text{NO}^+$  ion ratios (subsequently referred to as  $\text{NO}_x^+$  ratios) in the mass spectra observed. This method has been successfully used to analyze pON composition in several studies (Fry et al., 2013; Pye et al., 2015; Kiendler-Scharr et al., 2016; Ng et al., 2017; Fry et al., 2018; Huang et al., 2019a, b; Brownwood et al., 2021; Day et al., 2022a). The basis of the  $\text{NO}_x^+$  ratio method comes from the empirical observation that nitrates attached to an organic moiety have different fragmentation patterns in the mass spectrometer's vaporizer and ionizer compared to nitrate in the form  
40 of  $\text{NH}_4\text{NO}_3$ . Thus, inorganic and organic nitrates will have different  $\text{NO}_x^+$  ratios,  $R_\nu$ , as shown below in Eq. 1 (Day et al., 2002; Francisco and Krylowski, 2005; Farmer et al., 2010; Drewnick et al., 2015; Hu et al., 2016b; Day et al., 2022a).

$$R_\nu = \frac{(C_{\text{NO}_2^+})_\nu}{(C_{\text{NO}^+})_\nu} \quad (1)$$

$\nu$ : nitrate compound or mixture measured

The  $\text{NO}_x^+$  ratio of the observed air ( $R_{\text{obs}}$ ) falls between the  $\text{NO}_x^+$  ratios of pure pAmN ( $R_{\text{pAmN}}$ ) and pure pON ( $R_{\text{pON}}$ ). The  
45 time-varying mass fraction of particulate organic nitrate ( $f_{\text{pON}}$ , referring to  $\text{pNO}_3$  existing as pON), and particulate ammonium nitrate ( $f_{\text{pAmN}}$ , referring to  $\text{pNO}_3$  existing as pAmN) can be extracted from this time-varying  $R_{\text{obs}}$  using Eqs. 2 and 3 (Farmer

et al., 2010).

$$f_{\text{pON}} = \frac{(R_{\text{obs}} - R_{\text{pAmN}})(1 + R_{\text{pON}})}{(R_{\text{pON}} - R_{\text{pAmN}})(1 + R_{\text{obs}})} \quad (2)$$

$$f_{\text{pAmN}} = 1 - f_{\text{pON}} \quad (3)$$

50 The aerosol chemical speciation monitoring (ACSM; Aerodyne Inc.) is a unit-mass resolution (UMR) mass spectrometry instrument intended for continuous ambient aerosol monitoring (Ng et al., 2011; Fröhlich et al., 2013), unlike its predecessor, the aerosol mass spectrometer (AMS; Aerodyne Inc.) which is designed primarily for research (Drewnick et al., 2005). In this work, we explored whether the ACSM can be used to determine pAmN and pON in the same way as has been successfully demonstrated for the AMS. ACSMs are used extensively in monitoring networks, such as the sites in the Aerosol, Clouds and  
55 Trace Gases Research Infrastructure (ACTRIS) network in Europe (<https://www.psi.ch/en/acsm-stations/overview-full-period>, last access: 6 November 2024) and the Atmospheric Science and Chemistry mEasurement NeTwork (ASCENT) network in the USA (<https://ascent.research.gatech.edu>, last access: 6 November 2024).

For monitoring purposes, a capture vaporizer (CV) and an intermediate pressure lens (IPL) are recommended by Aerodyne for improved quantification, relative to a standard vaporizer (SV) and standard lens (Zheng et al., 2020). Almost half of  
60 the ACSMs in the ACTRIS network in Europe use CV. The CV is designed is to increase particle collision events with the vaporizer surface by having a narrow entrance, resulting in a particle collection efficiency (CE) of 1 and better mass closure of PM<sub>2.5</sub> monitoring (Jayne and Worsnop, 2016; Hu et al., 2017; Xu et al., 2017; Liu et al., 2024). The enhanced thermal decomposition, however, shifts the fragmentation pattern toward smaller ion fragments (Hu et al., 2017, 2018a; Xu et al., 2017; Zheng et al., 2020). Therefore, the NO<sub>x</sub><sup>+</sup> ratio is substantially lower with CV compared to SV due to favored NO<sup>+</sup> formation.  
65 In consequence, the NO<sub>x</sub><sup>+</sup> ratio method's applicability in CV-based measurements is limited by the NO<sub>2</sub><sup>+</sup> detection limit (<0.1 μg m<sup>-3</sup>; Hu et al. (2017)).

While high resolution mass spectrometers can separate non-NO<sub>x</sub><sup>+</sup> peaks which are detected at the same nominal *m/z* (mass-to-charge ratio) as NO<sub>x</sub><sup>+</sup> peaks (30 for NO<sup>+</sup> and 46 for NO<sub>2</sub><sup>+</sup>), UMR analysis requires estimations based on related ions at other  
70 *m/z*. These estimations are incorporated into data workup by the implementation of a fragmentation table, which subtracts an estimated amount of organic at *m/z* 30 and *m/z* 46, based on the signal at another related organic-only *m/z*. The default fragmentation table typically applied for the analysis of UMR spectra is based on generalized fragment mass composition of ambient aerosol composition measured using SV-based instruments (Allan et al., 2004; Ulbrich et al., 2009), and thus not suitable for CV-UMR-ToF spectra that have different fragmentation patterns. Using a CV-HR-ToF-AMS, Hu et al. (2017) determined the organic fragment interference to NO<sup>+</sup> in *m/z* 30 and to NO<sub>2</sub><sup>+</sup> in *m/z* 46 for CV-UMR measurements in a  
75 biogenically-dominated dataset, but no study has yet shown this calculation adapted to general ambient aerosol composition.

This work aims to adapt the NO<sub>x</sub><sup>+</sup> method to separate pAmN and pON signals to CV-UMR-ToF-ACSM measurements. We first provide a revised fragmentation table for *m/z* 30 and *m/z* 46 compatible with CV-UMR-ToF-ACSM measurements with varying composition to better calculate NO<sup>+</sup> and NO<sub>2</sub><sup>+</sup> concentrations. Second, we show the variation of empirical NO<sub>x</sub><sup>+</sup> ratio for pAmN in CV-UMR-ToF-ACSM instruments and determine the NO<sub>x</sub><sup>+</sup> ratio for pON. Third, we demonstrate the capability  
80 of data pre-treatments (filtering and time averaging) to overcome the low and noisy ratio signals produced by CV in ambient

measurements. Fourth, the proposed  $\text{NO}_x^+$  ratio method is applied to an extended ambient dataset (at the Cabauw site of the Ruisdael Observatory Network) to test its robustness for changing ambient aerosol mixtures. Lastly, the formation of pAmN and pON in a chamber experiment measured using CV-UMR-ToF-ACSM is used for method validation by comparing results with SV-HR-ToF-AMS.

## 85 2 Instrumentation

### 2.1 Description of ToF-ACSM

A ToF-ACSM (Aerodyne Inc.) is the main instrument used in this study, allowing the chemical analysis of non-refractory organics (Org), ammonium ( $\text{NH}_4$ ), nitrate ( $\text{NO}_3$ ), sulfate ( $\text{SO}_4$ ), and chloride (Chl) in the aerosol phase (Ng et al., 2011; Fröhlich et al., 2013). In comparison to compact time-of-flight (cToF)-AMS (Drewnick et al., 2005) and HR-ToF-AMS (DeCarlo et al., 90 2006), ToF-ACSM is more compact in size, lower in price and operational cost, simpler in analysis, and requires less user intervention, which makes this instrument practical for long-term monitoring but still comparable to the AMS (Fröhlich et al., 2013). ToF-ACSM uses a three-way valve system that allows automatic switching between the sample and filter mode, unlike ToF-AMS, which has a mechanical chopper that physically blocks the particle beam. The lack of a chopper (but with the use of particle time-of-flight chamber) in the ToF-ACSM, however, removes the particle sizing feature, which makes it similar to 95 the quadrupole-ACSM (Q-ACSM) but with better mass resolution and detection limits.

To conduct the various analyses in this paper, we primarily use data from two ToF-ACSM instruments with identical setup. The instruments are managed by Utrecht University (UU) and University of Groningen (RUG), part of a larger monitoring network of Ruisdael Observatory in the Netherlands (<https://ruisdael-observatory.nl>, last access: 6 November 2024). We label the instruments as ACSM-UU and ACSM-RUG. The instrument setup for ambient measurements uses a combination of a 100  $\text{PM}_{2.5}$  size-cut cyclone, an intermediate-pressure lens ( $\text{PM}_{2.5}$  aerodynamic lens), and a capture vaporizer (CV,  $\sim 525^\circ\text{C}$ , Jayne and Worsnop (2016)) that has been aligned to be centered on the vaporizer. Together, they configure the ToF-ACSM as a  $\text{PM}_{2.5}$  monitor (Xu et al., 2017) with unit mass resolution. The instrument provides UMR mass spectra with default 10 min time resolution, analyzed using Tofware v3.3 in Igor Pro 8. The fractions of the UMR signal are assigned to different aerosol species using the fragmentation table.

### 105 2.2 Ambient measurements with ACSM

We use an ambient dataset measured using ACSM-UU deployed in Cabauw, the Netherlands, for method development and case studies. The ambient data were measured between 18 April 2023 to 15 April 2024 with some gaps (net 205 days of data) as part of the continuous monitoring of the Ruisdael Observatory network. Aerosol measurements were carried out with an inlet height of 4.5 m above the ground at the Cabauw tower ( $51.97^\circ\text{N}$ ,  $4.93^\circ\text{E}$ ), an infrastructure of the Royal 110 Netherlands Meteorological Institute (KNMI, the Netherlands, <https://www.knmi.nl/home>, last access: 9 November 2024). The site is surrounded by agricultural lands in the province of Utrecht, the Netherlands, a relatively nitrogen-polluted rural site.

Ambient air is sampled through a stainless-steel inlet system with a PM<sub>2.5</sub> size-cut cyclone (URG-2000-30ED) and a Nafion dryer with a sampling flow rate of  $\sim 2 \text{ L min}^{-1}$ , of which in average  $1.23 \text{ cm}^3 \text{ s}^{-1}$  ( $0.07 \text{ L min}^{-1}$ ) is sampled by the ACSM. The calibrations of ionization efficiency (IE) and relative IE (RIE) were performed using 300 nm particles from ammonium nitrate (NH<sub>4</sub>NO<sub>3</sub>) and ammonium sulfate ((NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>) solutions (size-selected with a differential mobility analyzer, model TSI 3081 and co-sampled with a condensation particle counter, model TSI 3750). The average IE value for the instrument is 169 ions pg<sup>-1</sup> for NO<sub>3</sub>, and RIE values are 1.40, 1.58, 1.30, and 3.37 for Org, SO<sub>4</sub>, Chl, and NH<sub>4</sub>, respectively. RIE's used for Org and Chl were not measured, and instead applied as default values, as is common practice. The detection limits at 10 min time resolution are 0.38  $\mu\text{g m}^{-3}$  for Org, 0.12  $\mu\text{g m}^{-3}$  for NH<sub>4</sub>, 0.07  $\mu\text{g m}^{-3}$  for NO<sub>3</sub>, 0.07  $\mu\text{g m}^{-3}$  for NO<sup>+</sup> (*m/z* 30), 0.04  $\mu\text{g m}^{-3}$  for NO<sub>2</sub><sup>+</sup> (*m/z* 46), 0.11  $\mu\text{g m}^{-3}$  for SO<sub>4</sub>, and 0.09  $\mu\text{g m}^{-3}$  for Chl.

### 2.3 Chamber measurements with ACSM and AMS

ACSM-RUG was deployed to measure aerosol in chamber experiments conducted in Aerosol Interaction and Dynamics in the Atmosphere (AIDA) chamber, a facility maintained by Karlsruhe Institute of Technology (KIT), Germany. Chamber experiments were conducted in 2023 and 2024 as part of the Cloud-Aerosol Interactions in a Nitrogen-dominated Atmosphere (CAINA) project (<https://sites.google.com/view/cainaproject/>, last access: 6 November 2024).

Chamber air is sampled using stainless steel tubing equipped with a Nafion dryer and a sampling flow of  $\sim 2 \text{ L min}^{-1}$  of which in average  $1.44 \text{ cm}^3 \text{ s}^{-1}$  ( $0.09 \text{ L min}^{-1}$ ) is sampled by the ACSM. The average IE value for the instrument is 152 ions pg<sup>-1</sup> for NO<sub>3</sub>. The ACSM instrument is run with 2 min time resolution unlike the default setting to capture more variation in the aerosol composition. The detection limits at 2 min time resolution for the ACSM-RUG instrument are 0.20  $\mu\text{g m}^{-3}$  for Org, 0.19  $\mu\text{g m}^{-3}$  for NH<sub>4</sub>, 0.17  $\mu\text{g m}^{-3}$  for NO<sub>3</sub>, 0.17  $\mu\text{g m}^{-3}$  for NO<sup>+</sup> (*m/z* 30), 0.03  $\mu\text{g m}^{-3}$  for NO<sub>2</sub><sup>+</sup> (*m/z* 46), 0.02  $\mu\text{g m}^{-3}$  for SO<sub>4</sub>, and 0.05  $\mu\text{g m}^{-3}$  for Chl.

In addition, a high-resolution time-of-flight aerosol mass spectrometer (HR-AMS, Aerodyne Research Inc.) from KIT is connected to the chamber via a 6 mm (4 mm internal diameter) stainless steel tube. The instrument is equipped with a PM<sub>2.5</sub> aerodynamic lens to measure the non-refractory PM<sub>2.5</sub> components, at a time resolution of 1 min (DeCarlo et al., 2006; Canagaratna et al., 2007; Williams et al., 2013), averaged to 2 min for this comparison. The operation of the AMS is explained in previous publications (Huang et al., 2019a; Song et al., 2022). Briefly, chamber air is sampled with a flow of  $1.08 \text{ L min}^{-1}$ , of which in average  $84 \text{ cm}^3 \text{ min}^{-1}$  is sampled by the AMS (Gao et al., 2022). The aerosol particles are then focused into a narrow beam by a PM<sub>2.5</sub> aerodynamic lens with an effective complete transmission for particle sizes ranging from 70 to 2500 nm (vacuum aerodynamic diameter;  $D_{va}$ ) and heated by a standard vaporizer at 600 °C. The resulting vapors are ionized by electron impact (70 eV) and characterized by a time-of-flight mass spectrometer. The AMS ionization efficiency is calibrated using 300 nm dried NH<sub>4</sub>NO<sub>3</sub> aerosol particles to give an average IE NO<sub>3</sub> of 185.0 ions pg<sup>-1</sup>. The AMS data are analysed using the software packages SQUIRREL 1.66E and PIKA 1.26E in Igor Pro 8. To account for the effect of particle bouncing loss, chemical-composition-based collection efficiency (0.5) are applied to calculate the particle mass concentration (Middlebrook et al., 2012).

### 145 3 Development of a fragmentation table for CV-UMR-ToF-ACSM from AMS spectral database and ACSM chamber experiment spectra

#### 3.1 General fragmentation table for typical ambient dataset

In the UMR-ACSM instruments, ions detected at  $m/z$  30 and  $m/z$  46 can originate both from nitrate ( $\text{NO}^+$  and  $\text{NO}_2^+$ ) and organic fragments. However, it is known that some fragments produced by processes in the vaporizer and ionizer can be correlated to one another (Allan et al., 2004). For instance, UMR peaks at  $m/z$  29,  $m/z$  42,  $m/z$  43, and  $m/z$  45 are mainly the product of further fragmentation of fragments at  $m/z$  30 and  $m/z$  46 and assumed to be exclusively organic. The aim of the fragmentation table, with respect to the  $\text{NO}_x^+$  species, is to predict the mass concentration of organic fragments at  $m/z$  30 and  $m/z$  46 based on the masses measured at  $m/z$  29,  $m/z$  42,  $m/z$  43, and  $m/z$  45, and subsequently to extract the signal that can be attributed to  $\text{NO}^+$  and  $\text{NO}_2^+$ .

155 Our starting point is the default fragmentation table from Allan et al. (2004) (see Table 1). A fragmentation table consists of columns dividing the raw mass spectra into chemical species, with rows denoting entries for different UMR nominal masses. Thus, each entry consists of components which are added up to obtain the species concentration at a specific nominal mass. These components can be the whole peak of an  $m/z$   $x$ , referred to as an integer number (with square brackets in this paper, "[ $x$ ]"), or the contribution of a certain species to  $m/z$   $x$  in the fragmentation table, denoted as "frag\_species[ $x$ ]." A multiplier a (positive or negative) is added if the addition or subtraction of the component is fractional. The fragmentation table for ToF-AMS and ToF-ACSM are identical, except that gas-phase species contribution must also be removed in ToF-AMS. For the ACSM, due to the automatic filter sampling cycle and subtraction, gas-phase species are already removed. The fragmentation table developed in this paper, therefore, is applicable to any UMR aerosol mass spectrometer with a CV inlet.

**Table 1.** Excerpt of fragmentation table for Org and  $\text{NO}_3$  species in  $m/z$  30 and  $m/z$  46. Second and third column shows entries originated from the default fragmentation table of Allan et al. (2004) (used in Tofware v3.3). Fourth and fifth column shows entries proposed to develop revised CV-UMR-ToF-ACSM fragmentation table in this study.

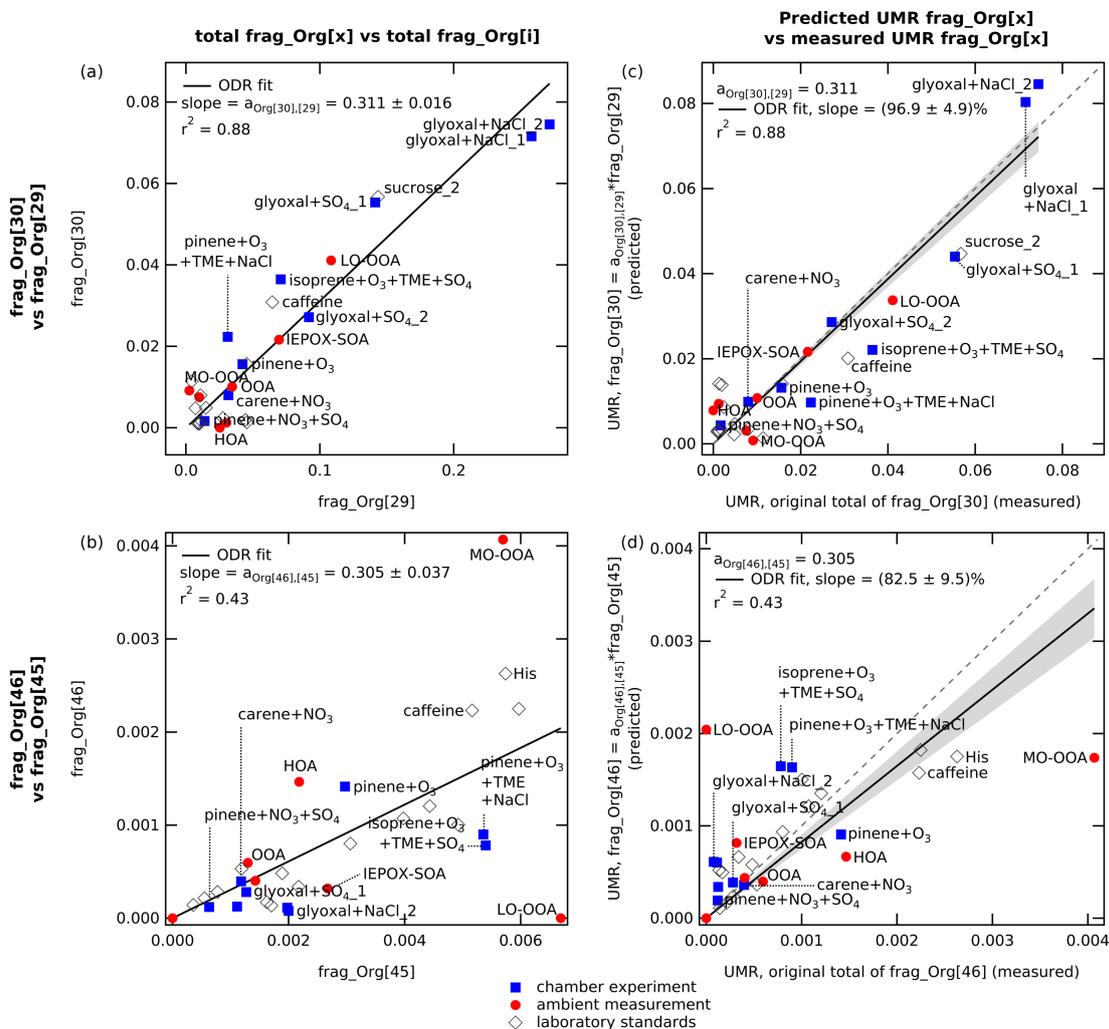

$m/z$	Allan et al. (2004), default fragmentation table		Proposed for general CV-ToF-ACSM	
	Org (a)	$\text{NO}_3$ (b)	Org (c)	$\text{NO}_3$ (d)
30	$0.022 \cdot \text{frag\_Org}[29]$	[30], -frag_Org[30]	$a_{\text{Org}[30],[i]} \cdot \text{frag\_Org}[i]$ <sup>(a)</sup>	[30], -frag_Org[30]
46	-	[46]	$a_{\text{Org}[46],[i]} \cdot \text{frag\_Org}[i]$ <sup>(b)</sup>	[46], -frag_Org[46]

$i$  represents UMR masses tested against  $m/z$  30 and  $m/z$  46 in this study, which includes frag\_Org[29], frag\_Org[42], frag\_Org[43], and frag\_Org[45]. See the list in the footnote of Table S3 of SI.

(a)  $a_{\text{Org}[30],[i]}$  is the multiplier for frag\_Org[30] component, obtained from the slope of ODR fit between frag\_Org[30] and frag\_Org[ $i$ ].

(b)  $a_{\text{Org}[46],[i]}$  is the multiplier for frag\_Org[46] component, obtained from the slope of ODR fit between frag\_Org[46] and frag\_Org[ $i$ ].

In the default fragmentation table (which was developed using an SV inlet), the signal at  $m/z$  46 is assigned exclusively to  $\text{NO}_2^+$ , and only a minor contribution of the signal at  $m/z$  29 (2.2%) is assumed to be correlated to the organic signal at  $m/z$  30. Fry et al. (2018) found substantially larger organic fragments at  $m/z$  30 and  $m/z$  46 than the default fragmentation table in

**Figure 1.** The left-hand panels show the best ODR fits (set to zero intercept) which are found in the correlation between the concentrations of (a) frag\_Org[30] vs frag\_Org[29], and (b) frag\_Org[46] vs frag\_Org[45]. The correlations of all mass pairs are summarized in Table S3. The right-hand panels show the predicted organic contributions (based on the new multipliers) at each  $m/z$  versus the measured amount. Plot (c) shows the predicted UMR frag\_Org[30] against the measured total Org fragments in  $m/z$  30, and plot (d) shows the predicted UMR frag\_Org[46] against the measured total Org fragments in  $m/z$  46. The figure demonstrates that the predicted frag\_Org[ $x$ ] slightly underestimates (slope = 0.83) but approached the measured frag\_Org[ $x$ ].

a semi-polluted biogenically-influenced air analyzed with an SV-HR-ToF-AMS. Switching from SV to CV can also modify the concentration ratio between organic and inorganic fragments at  $m/z$  30 and  $m/z$  46, because of greater organic fragmentation in CV (Hu et al., 2018a). Therefore, modifications to frag\_NO<sub>3</sub>[46] and frag\_NO<sub>3</sub>[30] entries (later referred to as  $C_{NO_2^+}$  and  $C_{NO^+}$  to calculate NO<sub>x</sub><sup>+</sup> ratio outside fragmentation table context) must be established for CV-based instruments.

To make a revised fragmentation table applicable for general ambient SOA mixtures, a variety of organic aerosol profiles is necessary. We use 25 CV-HR-ToF-AMS spectra (including both nitrates and non-nitrate organics) from the AMS spectral database ([http://cires1.colorado.edu/jimenez-group/AMSsd\\_CV](http://cires1.colorado.edu/jimenez-group/AMSsd_CV), last access: 6 November 2024) and 6 CV-UMR-ToF-ACSM spectra from chamber experiments. The CV-HR-ToF-AMS database mass spectra include 3 chamber experiments, 7 factors of positive matrix factorization (PMF) analysis from ambient measurements, and 15 laboratory standards measurements (Hu et al., 2017; Carlton et al., 2018; Hu et al., 2018a, b), summarized in Table S1 in the Supplementary Information (SI). The CV-UMR-ToF-ACSM mass spectra were measured from experiments conducted in the AIDA chamber (see Section 2.3).

Using these data, we determine the multipliers  $a$  used in a revised calculation of frag\_Org[30] and frag\_Org[46] (see Table S1, third and fourth column). The new multipliers are determined by performing orthogonal distance regression (ODR) constrained to a zero intercept of mass spectra in UMR. For HR-AMS spectra, the dataset is "degraded" from HR into UMR spectra by summing HR Org fragments to their respective nominal mass in each AMS spectrum. Note that for UMR-ACSM spectra, because we cannot separate species at the same nominal  $m/z$ , we only use chamber experiments that are assumed nitrate-free or to contain negligible nitrate (no seed or precursor for inorganic and organic nitrate). Therefore, all signals at  $m/z$  30 and  $m/z$  46 are exclusively organic fragments. We perform ODR fits of frag\_Org[30] and frag\_Org[46] against a list of chemically related masses (frag\_Org[ $i$ ]). The slope of the ODR fits to determine the multiplier  $a_{\text{Org}[30],[i]}$  and  $a_{\text{Org}[46],[i]}$  are summarized in Table S3, alongside the list of fragments of  $i$  that contribute to each nominal mass, in the footnote. Fig. 1a shows that frag\_Org[30] is best correlated with frag\_Org[29], where  $a_{\text{Org}[30],[29]} = 0.311 \pm 0.016$  (mean  $\pm$  uncertainty,  $r^2 = 0.88$ ). On the other hand, Fig. 1b shows that frag\_Org[46] is correlated best with frag\_Org[45], compared to other frag\_Org[ $i$ ], where  $a_{\text{Org}[46],[45]} = 0.305 \pm 0.037$  (mean  $\pm$  uncertainty,  $r^2 = 0.43$ ). The final revised fragmentation table in CV-UMR-ToF-ACSM is summarized in the conclusions (see Table 4).

We apply these new multiplier values to the full dataset and compare the results with those from multipliers described in Allan et al. (2004), the SI of Fry et al. (2018), and the SI of Hu et al. (2017) (see in Table S4). The result suggests that the multiplier  $a_{\text{Org}[46],[45]}$  determined here gives the best predicted frag\_Org[46] over multipliers from other studies (see Fig. 1c,d and Table S4 third and seventh columns in the SI). Meanwhile, the multiplier  $a_{\text{Org}[30],[29]}$  determined here performs similarly with the multipliers obtained from Hu et al. (2017) (SV and CV) for a dataset dominated by biogenic SOA. The plot of predicted UMR frag\_Org[30] against the measured total Org fragments in  $m/z$  30 (see Fig. 1c) shows that the multiplier determined here is able to estimate on average  $96.9 \pm 4.9\%$  of the measured frag\_Org[30]. Meanwhile, the similar plot for frag\_Org[46] against the measured total Org fragments in  $m/z$  46 (see Fig. 1d) shows that the multiplier determined here estimates on average  $82.5 \pm 9.5\%$  of the measured frag\_Org[46]. The low concentration of both  $m/z$  46 and  $m/z$  45 may cause this underestimation and suggests that frag\_Org[46] and frag\_Org[45] may have a more complicated relationship; their correlation may vary substantially depending on the aerosol mixture. Therefore, it may be appropriate to modify the entry for frag\_NO<sub>3</sub>[46] according to the type of aerosol mixture analyzed. On the other hand, for complex ambient mixtures, the ensemble composition may produce spectra that are more similar to the average determined here. Analysis of CV-HR spectra from a variety of ambient samples would be required to determine the actual variation of organic contributions at  $m/z$  46.

## 205 3.2 Composition-specific fragmentation table

The multipliers determined in Section 3.1 are designated for typical ambient aerosol composition. In some cases, a composition-specific fragmentation table may be more appropriate to use. For instance, from a field study with biogenically-dominated composition, Hu et al. (2017) reported  $a_{\text{Org}[30],[29]} = 0.32$  and  $a_{\text{Org}[46],[45]} = 0.68$ . By using selected chamber experiments in the same dataset, we can explore different multipliers that are compatible for different composition profiles. For chamber experiments that involves glyoxal (and its oligomers), we obtain  $a_{\text{Org}[30],[29]} = 0.291 \pm 0.022$  (mean  $\pm$  uncertainty,  $n = 4$ ,  $r^2 = 0.90$ ) and  $a_{\text{Org}[46],[45]} = 0.082 \pm 0.036$  (mean  $\pm$  standard deviation,  $n = 4$ ,  $r^2 = 0.35$ ). For chamber experiments that involve only terpenes (e.g., isoprene,  $\alpha$ -pinene), we obtain  $a_{\text{Org}[30],[29]} = 0.476 \pm 0.067$  (mean  $\pm$  uncertainty,  $n = 5$ ,  $r^2 = 0.82$ ) and  $a_{\text{Org}[46],[45]} = 0.204 \pm 0.055$  (mean  $\pm$  uncertainty,  $n = 5$ ,  $r^2 = 0.33$ ) which can be applied for chamber experiments with terpene as precursor. The ODR fit plots are given in Fig. S1. The multipliers to revise the fragmentation table in CV-UMR-ToF-ACSM for specific aerosol composition subsets is summarized in the conclusions (see Table 4).

## 4 Determination of $\text{NO}_x^+$ ratios for the CV-UMR-ToF-ACSM

### 4.1 $\text{NO}_x^+$ ratio of pure pAmN

To quantify the inorganic  $\text{NO}_x^+$  ratio typical value and variability produced by the CV, we use repeated measurements from regular pAmN calibration from the two ACSM instruments described in Section 2. The  $R_{\text{pAmN}}$  of ACSM-UU is found to be 220  $0.0237 \pm 0.0009$  (mean  $\pm$  uncertainty,  $n = 5$ ), and  $R_{\text{pAmN}}$  of ACSM-RUG is  $0.0115 \pm 0.0002$  (mean  $\pm$  uncertainty,  $n = 3$ ). The values are similar but lower than other studies where  $R_{\text{pAmN}}$  with CV was found to be 0.04-0.07 (Hu et al., 2016a), and all are  $\sim 10$  times lower than the typical  $R_{\text{pAmN}}$  measured with the SV, 0.3-0.7 (Day et al., 2022b). We found that  $R_{\text{pAmN}}$  values are very consistent for each instrument over time. A summary of  $R_{\text{pAmN}}$  values and regression fit parameters from each measurement can be found in Table S5 in the SI.

225 Hu et al. (2017) found that the  $\text{NO}_x^+$  ratio is affected by the aerodynamic lens alignment. The influence is greater in the CV since the vaporizer opening diameter is  $\sim 2.5$  mm (SI of Hu et al. (2018b)), smaller than that of SV, which is  $\sim 3.8$  mm (Drewnick et al., 2005). For optimum particle detection, the aerodynamic lens must point the particle beam at the center of the vaporizer. Directed into the center, the particles enter the CV cavity and experience augmented thermal decomposition, at which the  $\text{NO}_2^+$  concentration is at its minimum, while the  $\text{NO}^+$  concentration is highest. The  $\text{NO}_2^+$  concentration increases as 230 the particle beam moves closer to the edge of the vaporizer, where the thermal decomposition is not as extensive as in the center, resembling how the SV works. Thus, it is important to consider performing lens alignment to obtain the correct result for the  $\text{NO}_x^+$  ratio method. Monitoring the behavior of  $m/z$  30 and  $m/z$  46 in during pAmN calibration is a good way to determine whether the aerodynamic lens is well aligned. Combining the result of this study and the  $R_{\text{pAmN}}$  range in Hu et al. (2017), value of  $R_{\text{pAmN}}$  in the range of 0.01-0.07 can be used as reference to indicate properly aligned lens. Plotting the profile of the  $\text{NO}_x^+$  235 ratio with movement in both the vertical and horizontal directions obtained during the alignment is the best diagnostic.

## 4.2 $\text{NO}_x^+$ ratio of pure pON

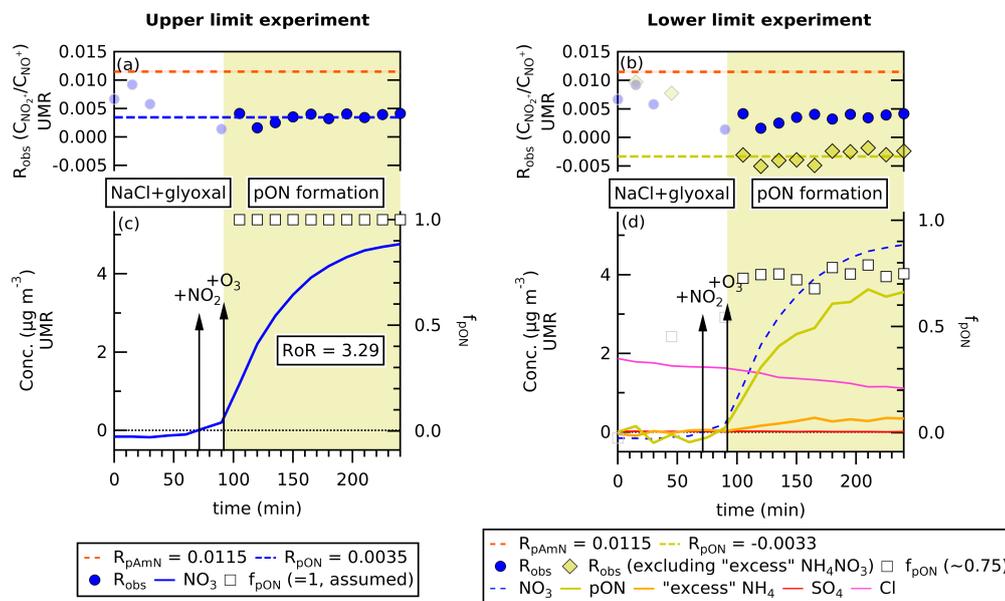

To obtain a  $\text{NO}_x^+$  ratio for pON, one would ideally measure pure atmospherically-relevant ON, prepared through synthesis or in a chamber experiment. Often, such standards are not available and therefore experimental  $R_{\text{pON}}$  cannot be easily determined for each instrument. To overcome this challenge, Day et al. (2022a) used the strategy of a "ratio-of-ratios" ( $RoR = R_{\text{pAmN}}/R_{\text{pON}}$ ) which can be used to calculate  $R_{\text{pON}}$  for any arbitrary instrument from its routinely-measured  $R_{\text{pAmN}}$ , and an average value for the RoR measured across many instruments under varying conditions. Day et al. (2022a) found that based on the relationship between  $R_{\text{pAmN}}$  and  $R_{\text{pON}}$  over a large range of measurement conditions, SV produces RoR of  $2.75 \pm 0.41$  (mean  $\pm$  uncertainty).

There have not been enough studies yet that have determined  $R_{\text{pON}}$  values in CV-based instruments in order to determine a robust  $RoR$  estimate for CV instruments. In the work of Hu et al. (2017), a chamber experiment producing pure pON yielded  $R_{\text{pON}} = 0.0045$ , and with comparison to  $R_{\text{pAmN}} = 0.06$  of their instrument, the value  $RoR = 13.3$  is obtained. With  $R_{\text{pAmN}}$  being 0.01 in CV as found in this study, using this  $RoR$  of 13.3,  $R_{\text{pON}}$  would be 0.0008 (approaching zero).

Similar to the approach of Kiendler-Scharr et al. (2016) that used the minimum measured value of  $\text{NO}_x^+$  ratio to set a fixed  $R_{\text{pON}}$  value, to estimate  $R_{\text{pON}}$ , we use the lowest measured  $\text{NO}_x^+$  ratio from a chamber experiment in which we expected to produce pON, with no inorganic nitrate present. The selected experiment used glyoxal as SOA precursor,  $\text{NO}_2$  and  $\text{O}_3$  to produce  $\text{NO}_3$  radical as the major oxidant, and sodium chloride (NaCl) seed to form SOA containing organic nitrates at 90% relative humidity. This experiment was conducted in the AIDA chamber at IMK KIT, Germany as part of CAINA project. For the spectra analysis, we use the fragmentation table specific for glyoxal-related chamber experiment, as described in Section 3.2.

While this experiment should produce pure organic nitrate aerosol, during pON formation, we observe an increase in  $\text{NH}_4$  which could happen for two reasons. First, ammonium nitrate impurities can be formed from reactions or chamber wall re-partitioning. Second, particulate water can be incorrectly assigned as  $\text{NH}_4$  through fragmentation table correction at the  $m/z$  16 and  $m/z$  17 (see complete fragmentation table in Allan et al. (2004)). Both can result in a higher  $\text{NO}_x^+$  ratio than as we would have if the total nitrate were purely pON. Therefore, we derive two bounding  $R_{\text{pON}}$  values from the glyoxal chamber experiment. First, we determine the  $R_{\text{pON}}$  from the experiment by assuming pure pON formation to obtain an upper limit. Second, to obtain the lower limit of  $R_{\text{pON}}$ , we assume all observed  $\text{NH}_4$  increase is  $\text{NH}_4\text{NO}_3$  aerosol and subtract this equivalent amount of inorganic nitrate, with the inorganic  $\text{NO}_x^+$  ratio, from the total  $\text{NO}_3$ , in order to obtain a lower limit of pON time series and calculate the  $R_{\text{pON}}$ . This strategy has been described as the "excess  $\text{NH}_4$ " method in Takeuchi and Ng (2019). By rearranging the Eq. 2 to Eq. S2, we can obtain  $R_{\text{pON}}$  using  $f_{\text{pON}}$ ,  $R_{\text{pAmN}}$ , and  $R_{\text{obs}}$  for the lower limit experiment (see details in Section S3 of SI).

The upper limit experiment gives  $R_{\text{pON}} = 0.0035$  (see Fig. 2a). If we compare to  $R_{\text{pAmN}} = 0.0115 \pm 0.0002$  (measured separately with pure AmN),  $R_{\text{pON}} = 0.0035$  obtained from the upper limit experiment gives  $RoR = 3.29$  (see Fig. 2a). This value is higher than  $RoR$  for SV-AMS but lower than  $RoR$  obtained from Hu et al. (2017).

**Figure 2.** The time series of (a and b)  $NO_x^+$  ratio, (c and d) ACSM species concentration (in  $\mu\text{g m}^{-3}$ , left bottom axis), and  $f_{pON}$  (right bottom axis) of glyoxal+ $NO_3$  chamber experiment at 15 min time averaging. The UMR fragmentation table specific for glyoxal is used to obtain  $C_{NO^+}$  and  $C_{NO_2^+}$ . Panels (c) and (d) shows the progression of p $NO_3$  formation alongside the  $NO_x^+$  ratio during the formation of pON. By averaging  $R_{obs}$  after pON formation started, the left-hand panel shows that  $R_{pON} = 0.0035$  is obtained when assuming  $f_{pON} = 1$ . When possible inorganic impurity is removed by assuming “excess”  $NH_4$  are  $NH_4NO_3$ , the average  $f_{pON}$  is found to be 0.75. The excess  $NH_4$  concentration is obtained by subtracting total  $NH_4$  concentration by the average  $NH_4$  concentration before the addition of  $NO_2$  and  $O_3$  (to exclude any possible  $NH_4Cl$  contribution). By calculating  $R_{pON}$  using the obtained  $f_{pON}$  from “excess  $NH_4$ ” method,  $R_{pAmN}$  and  $R_{obs}$ , the value  $R_{pON} = -0.0033$  is obtained, suggesting an overcorrection (see text). The value  $R_{pON} = 0.0035$  from the lower limit experiment and  $R_{pAmN} = 0.0115 \pm 0.0002$  (mean  $\pm$  uncertainty) give a ratio-of-ratios ( $RoR = R_{pAmN}/R_{pON}$ ) of 3.29.

On the other hand, the lower limit experiment gives  $R_{pON} = -0.0033$  (see Fig. 2b). A negative (or below zero)  $R_{pON}$  value is not chemically possible for concentration ratio. This value indicates an overcorrection, or that  $R_{pON}$  is varying around the zero value (small positive and negative) when the air mixture is strictly inorganic nitrate free. Thus, for calculation purposes, we use  $R_{pON} = 0.0001$  to represent the smallest possible  $NO_x^+$  ratio for CV-ACSM measurements.

As the  $RoR$  from the experiments (including Hu et al. (2017),  $RoR = 13.3$ ) are very different, we set the upper limit of  $R_{pON}$  to be  $R_{pON}$  obtained using  $RoR = 3.29$ , and the lower limit to be  $R_{pON} = 0.0001$  in CV. The calculated  $R_{pON}$  for two CV-ToF-ACSM deployed in this study are summarized in Table 2. These limits are used to determine the uncertainty of  $f_{pON}$  calculation. We use the geometric mean to establish the expected central value of  $R_{pON}$  in the dataset.

Since the  $R_{pAmN}$  values are quite different for the two ACSMs used in this study as we see in Table 2, the upper limit  $R_{pON}$  are also different by almost a factor of 2. However, since the lower limit of  $R_{pON}$  approaches zero, the geometric means of the upper and lower limits for the two instruments differ by only 25%. While calibrating every instrument with a pure

**Table 2.** Summary of measured  $R_{pAmN}$  (including uncertainties) and calculated  $R_{pON}$  (upper and lower limits as determined from pON in glyoxal+NO<sub>3</sub> chamber experiment). The geometric mean is considered as central value since  $R_{pON}$  is likely approaching zero. Values are for ACSM-UU (employed for ambient measurements in Cabauw) and the ACSM-RUG (employed for AIDA chamber experiments).

Instrument Measurements	ACSM-UU Cabauw ambient air		ACSM-RUG chamber experiment	
	$R_{pAmN}$	$R_{pON}$	$R_{pAmN}$	$R_{pON}$
Upper limit		0.0072 <sup>(a)</sup>		0.0035 <sup>(b)</sup>
Geometric mean	0.0237 ± 0.0009	0.0008 <sup>(c)</sup>	0.0115 ± 0.0002	0.0006 <sup>(c)</sup>
Lower limit		0.0001 <sup>(d)</sup>		0.0001 <sup>(d)</sup>

<sup>(a)</sup> Calculated using  $RoR = 3.29$ . The  $RoR$  is obtained using  $R_{pON}$  from the upper limit experiment of glyoxal+NO<sub>3</sub> and measured  $R_{pAmN}$ , using ACSM-RUG (see Fig. 2).

<sup>(b)</sup> Experimental NO<sub>x</sub><sup>+</sup> ratio value from the lower limit experiment of glyoxal+NO<sub>3</sub> using ACSM-RUG (see Fig. 2a).

<sup>(c)</sup> Geometric mean of the upper and lower limit  $R_{pON}$ .

<sup>(d)</sup> Set as the lowest possible NO<sub>x</sub><sup>+</sup> ratio in CV-based instruments, approaching zero.

280 organic nitrate aerosol standard would be a preferable way to establish  $R_{pON}$ , we recognize the unlikelihood of that for all monitoring ACSMs. Therefore, we recommend this  $RoR$ -based approach. As will be shown in the following section, despite the uncertainties outlined here based on potential impurities in our “pure pON” chamber experiment, the nitrate splitting performs encouragingly well, with both ACSMs.

## 5 Development of NO<sub>x</sub><sup>+</sup> ratio method for CV-UMR-ToF-ACSM

### 285 5.1 Challenges in NO<sub>x</sub><sup>+</sup> ratio method application to CV-UMR-ToF-ACSM dataset

Applying the NO<sub>x</sub><sup>+</sup> ratio method to separate pAmN and pON in CV-UMR-ToF-ACSM datasets is a greater challenge than with SV inlets, due primarily to the higher detection limit of NO<sub>3</sub>. The detection limit of pNO<sub>3</sub> in CV-UMR-ToF-ACSM is 0.01-0.08 μg m<sup>-3</sup> (from this work and Zheng et al. (2020) converted), around 10-100 times higher compared to those in SV-cToF-AMS (~0.6 ng m<sup>-3</sup> from Drewnick et al. (2009)) and SV-HR-ToF-AMS (0.1-4.0 ng m<sup>-3</sup> from DeCarlo et al. (2006)),  
 290 all converted to 10 min time resolution.

The poor detection limit for NO<sub>x</sub><sup>+</sup> ratios in CV-ToF-ACSM results from the low signal for  $m/z$  46 relative to  $m/z$  30 that are used to calculate frag\_NO<sub>3</sub>[30] ( $C_{NO^+}$ ) and frag\_NO<sub>3</sub>[46] ( $C_{NO_2^+}$ ). For instance, using the ACSM-UU, the detection limits of NO<sub>2</sub><sup>+</sup> and NO<sup>+</sup> are comparable ( $C_{DL,NO_2^+} = 0.044$  μg m<sup>-3</sup>;  $C_{DL,NO^+} = 0.066$  μg m<sup>-3</sup>; both in 10 min time resolution). However, the magnitude of observed NO<sub>2</sub><sup>+</sup> from ambient measurements is 25-500 times lower than NO<sup>+</sup> in CV-ToF-ACSM.  
 295 This means the NO<sub>2</sub><sup>+</sup> concentration is regularly close to the detection limit, particularly when the total pNO<sub>3</sub> concentration is low. This behavior also leads to noisy  $R_{obs}$ , due to a computation of very low or negative NO<sub>2</sub><sup>+</sup> concentrations, poor baseline, or both.

## 5.2 Data pre-treatment: Time averaging and data filtering

To determine which data points are reliable for  $R_{\text{obs}}$  calculation in the dataset, we could discard observed  $\text{NO}_2^+$  concentration that are below the detection limit. However, this would result in removing nearly all the data, including data that, while low and noisy, can still provide quantitative information with adequate averaging. Therefore, we use observed  $\text{NO}^+$  ion concentrations as the filtering parameter. The  $\text{NO}^+$  concentration accounts for  $\sim 95\%$  of the total concentration of  $\text{NO}_3$  species measured by ToF-ACSM (no RIE applied), and thus is a good indicator of when both  $\text{NO}^+$  and  $\text{NO}_2^+$  concentrations are too uncertain.

Eq. 4 describes the  $\text{NO}^+$  concentration limit ( $C_{\text{NO}^+, \text{lim}}$ ) which assures reliable separation of  $f_{\text{pON}}$  and  $f_{\text{pAmN}}$  calculated using the detection limit of  $\text{NO}_2^+$  ( $C_{\text{DL}, \text{NO}_2^+}$ ) and  $R_{\text{pAmN}}$  as filter  $\text{NO}_x^+$  ratio. We choose the larger  $R_{\text{pAmN}}$  value, which is a less strict limit relative to  $R_{\text{pON}}$  value, but still keeps any data with sufficiently good signal-to-noise ratio to have measurable inorganic nitrate (having a reliable  $f_{\text{pAmN}}$ , which means reliable  $f_{\text{pON}}$ ). The measured data points with observed  $\text{NO}^+$  concentration below these criteria are replaced with not-a-number (nan).

$$C_{\text{NO}^+, \text{lim}} = \frac{C_{\text{DL}, \text{NO}_2^+}}{R_{\text{pAmN}}} \quad (4)$$

On this basis, we recommend data pre-treatments by time averaging and data filtering using observed  $\text{NO}^+$  concentration as parameter. Time averaging over longer time periods allows the reduction of the electronic noise coming from the instrument response and low counting statistics associated with sampling ambient air. Meanwhile, the data filtering serves to determine the minimum  $\text{pNO}_3$  concentration at which reliable  $R_{\text{obs}}$  can be obtained to calculate  $f_{\text{pON}}$  and  $f_{\text{pAmN}}$ .

The values of  $C_{\text{DL}, \text{NO}_2^+}$  and  $C_{\text{NO}^+, \text{lim}}$  in different time averaging are evaluated in Table 3 for the CV-ToF-ACSM deployed for ambient measurements in Cabauw, the Netherlands. The concentration limit is lower as the time resolution increases due to the improvement of detection limit with better statistics. For measurements in this study, the minimum reliable  $C_{\text{NO}^+}$  for 10 min, 30 min, 60 min, and 120 min time resolution are 1.88, 1.08, 0.77, and  $0.54 \mu\text{g m}^{-3}$ , respectively.

With these  $C_{\text{NO}^+, \text{lim}}$ , we performed data filtering to the ambient measurement time series from Cabauw in different averaging of the time series. The time averaging (generated by Tofware v3.3) is applied first before the data filtering to maximize retained data in the concentration average.

**Table 3.** Detection limits of  $\text{NO}_2^+$  and concentration limits for  $\text{NO}^+$  across different time averaging with  $R_{\text{pAmN}}$  as filter  $\text{NO}_x^+$  ratio for the CV-UMR-ToF-ACSM deployed for ambient measurements in the rural site of Cabauw, the Netherlands (ACSM-UU).

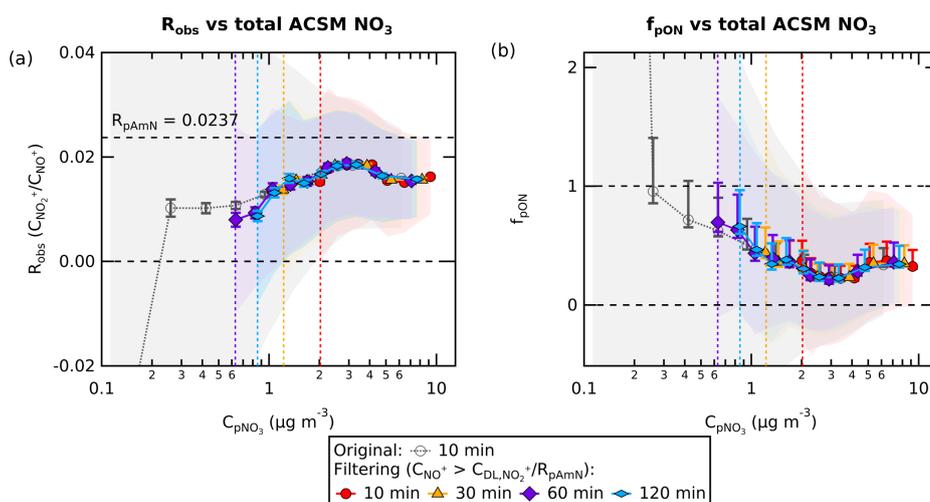

Concentration ( $\mu\text{g m}^{-3}$ )	10 min	30 min	60 min	120 min
$C_{\text{DL}, \text{NO}_2^+}$	0.044	0.026	0.018	0.013
$C_{\text{NO}^+, \text{lim}}$ (filter: $R_{\text{pAmN}} = 0.0237$ )	1.88	1.08	0.77	0.54

Chemical coordinate plots of  $R_{\text{obs}}$  and  $f_{\text{pON}}$  against the total concentration of particulate nitrate ( $C_{\text{pNO}_3}$ ) are shown in Fig. 3. These plots show the quantile average of the output variable on the y-axis (i.e.  $R_{\text{obs}}$  or  $f_{\text{pON}}$ ) as a function of concentration bins in the x-axis ( $C_{\text{pNO}_3}$ ). Fig. 3a,b shows that data filtering removes extreme  $R_{\text{obs}}$  and  $f_{\text{pON}}$  values near detection limit level.

The fact that the chemical coordinate trends are consistent across different averaging times indicates that filtering to remove  
 325 noisy data will not bias the interpretation of the ensemble dataset.

The combination of data filtering and time averaging shows an improvement in the minimum concentration reliable for  
 calculation ( $p\text{NO}_3$  concentration limit, vertical dashed lines) due to the improvement of  $C_{\text{DL},\text{NO}_2^+}$ . For measurements in this  
 study, the minimum reliable  $C_{p\text{NO}_3}$  for 10 min, 30 min, 60 min, and 120 min time averaging are 2.0, 1.2, 0.9, and 0.6  
 $\mu\text{g m}^{-3}$ , respectively. This result suggests that the  $\text{NO}_x^+$  ratio method in CV-UMR-ToF-ACSM is more reliable to analyze  
 330 nitrate pollution episodes or chamber experiments, and not for low background  $p\text{NO}_3$  concentrations. Because there is a trade-  
 off between time resolution and minimum reliable concentrations, for a given dataset, the timescale of typical variations should  
 be assessed in order to determine the appropriate averaging time.

**Figure 3.** Chemical coordinate plots (a) between  $R_{\text{obs}}$  against  $C_{p\text{NO}_3}$  in Cabauw, and (b) between the  $f_{\text{pON}}$  calculated using geometric mean of  $R_{\text{pON}}$  ( $R_{\text{pON}} = 0.0008$ ) against  $C_{p\text{NO}_3}$ . The revised fragmentation table for typical ambient dataset is used to obtain  $C_{\text{NO}^+}$  and  $C_{\text{NO}_2^+}$ . The line and marker traces represent the quantile average. The colored shading represents the standard deviation of each quantile while the whisker is the standard error. The standard deviation and standard error both include the uncertainty of ion counting statistics from measurements and uncertainty from ODR fit slope of fragmentation table correction. For  $f_{\text{pON}}$  (plot b), the standard deviation and standard error also include the uncertainty from lower and upper limit of  $R_{\text{pON}}$  ( $R_{\text{pON}} = 0.0001$ ;  $R_{\text{pON}} = 0.0072$ ). All analyses were done using the 10 min, 30 min, 60 min, and 120 min averaging of the time series, with data filtering. The original 10 min data without pre-treatment is also included as comparison. The combination of data filtering and time averaging reduces the noise compared to original data and improves the minimum concentration reliable for apportionment calculation ( $p\text{NO}_3$  concentration limit for each time average, as indicated with vertical dashed lines).

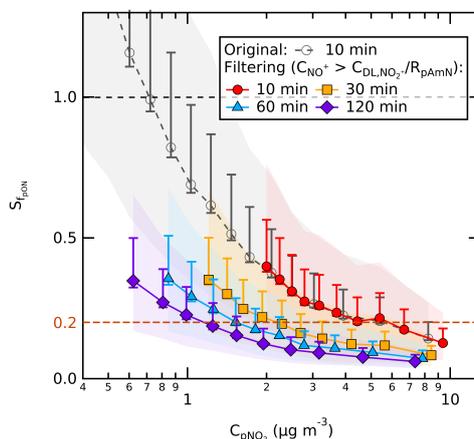

### 5.3 Error propagation

We propagated uncertainties from the variables in  $f_{\text{pON}}$  using simplified propagation of uncertainties using standard error (Day et al. (2023); see Section S4.3 of SI for details). The uncertainty of the final function ( $s_f$ ) is calculated using the standard error ( $s_{x_i}$ ) and partial derivative of the function ( $\frac{\partial f}{\partial x_i}$ ) of each measurand ( $x_i$ ) using Eq. 5.

$$s_{f(x_i, x_{i+1}, \dots)} = \sqrt{\sum_{i=1}^N \left( \frac{\partial f(x_i, x_{i+1}, \dots)}{\partial x_i} \right)^2 \cdot s_{x_i}^2} \quad (5)$$

The uncertainty of  $f_{\text{pON}}$  arises from three terms:  $R_{\text{obs}}$ ,  $R_{\text{pAmN}}$ , and  $R_{\text{pON}}$ . For  $R_{\text{obs}}$ , the uncertainty is further composed of 6 components that make up  $\text{NO}^+$  and  $\text{NO}_2^+$  concentrations (the uncertainties of  $m/z$  29,  $m/z$  30,  $m/z$  45, and  $m/z$  46 related to precision uncertainty from electronic noise and ion counting statistics, and the uncertainties of the fragmentation table multipliers, represented by the uncertainty of ODR fit slope. For  $R_{\text{pAmN}}$ , we propagate the uncertainty of the mean  $\text{NO}_x^+$  ratio from repeated  $\text{NH}_4\text{NO}_3$  measurements using ODR fit to consider the instrument stability in acquiring the  $\text{NO}_x^+$  ratio over time. For  $R_{\text{pON}}$ , the uncertainty is set to zero. Instead, the lower and upper limit of  $R_{\text{pON}}$  (see Table 2) serve to give a range of final propagated uncertainty, which includes  $R_{\text{obs}}$ ,  $R_{\text{pAmN}}$ , and  $R_{\text{pON}}$ .

**Figure 4.** The chemical coordinate plot (quantile average) between  $s_{f_{\text{pON}}}$  and  $C_{\text{pNO}_3}$  with  $R_{\text{pAmN}} = 0.0237$  as filter  $\text{NO}_x^+$  ratio at various averaging of the time series. The line and marker trace represents the average uncertainty produced from the geometric mean of  $f_{\text{pON}}$ . The uncertainty consists of uncertainties of ion counting statistics from measurements, uncertainty from ODR fit slope of fragmentation table correction, and uncertainty of  $R_{\text{pAmN}}$ . The colored shading represents the standard deviation of each quantile, while the whisker is the standard error. The shading and whisker both include the uncertainty of  $R_{\text{pON}}$  coming from the lower and upper limit of  $R_{\text{pON}}$  ( $R_{\text{pON}} = 0.0001$  and  $R_{\text{pON}} = 0.0072$ ), and also the uncertainty of the average quantile. In general, data pre-treatment improves the  $\text{pNO}_3$  concentration limit of reliable measurements (below  $\pm 0.5$  uncertainty) for each time-fold of averaging. Uncertainties of  $f_{\text{pON}} < 0.2$  (absolute value) is reached at  $\text{pNO}_3$  concentration of  $7 \mu\text{g m}^{-3}$  for 10 min averaging, while at 60 min, it is reached already at concentrations of  $2 \mu\text{g m}^{-3}$ .

345 Fig. 4 shows that low  $p\text{NO}_3$  concentrations produce larger uncertainties in  $f_{\text{pON}}$  ( $s_{\text{pON}}$ ) compared to higher concentrations. If we compare the analysis with and without data filtering, we observe that filtering targets data points with high absolute  $s_{\text{pON}}$  (above  $\pm 0.5$ ). We avoid removing many data points in the low concentration range by performing time averaging, where the average uncertainty decreases by  $\sim \sqrt{N}$  for each  $N$ -fold of averaging from 10 min. Meanwhile, the uncertainties from  $R_{\text{pAmN}}$  and  $R_{\text{pON}}$  ( $RoR$ ) remain unaffected by time averaging because the values remain constant in the time series.

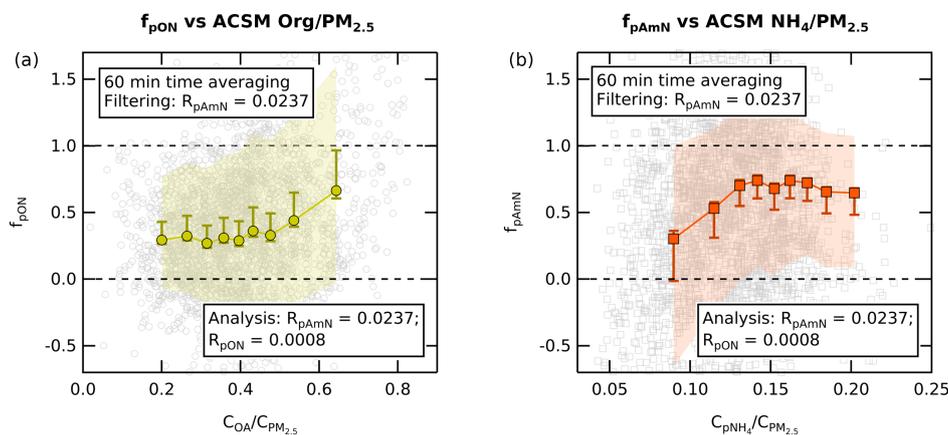

350 If we use the lower range of  $f_{\text{pON}}$  in China (17%) described by Yu et al. (2024) as reference for the minimum uncertainty needed for reporting reliable  $f_{\text{pON}}$ , we can observe that the lowest  $p\text{NO}_3$  where we obtain below  $\pm 0.2$  uncertainty decreases along with time averaging as well. For the original 10 min data, uncertainties below  $\pm 0.2$  is reached at  $p\text{NO}_3$  concentration  $> 7 \mu\text{g m}^{-3}$ , while at 60 min time averaging, it is reached already at concentration of  $2 \mu\text{g m}^{-3}$ .

## 6 Case studies demonstrating $\text{NO}_x^+$ ratio method for CV-ToF-ACSM

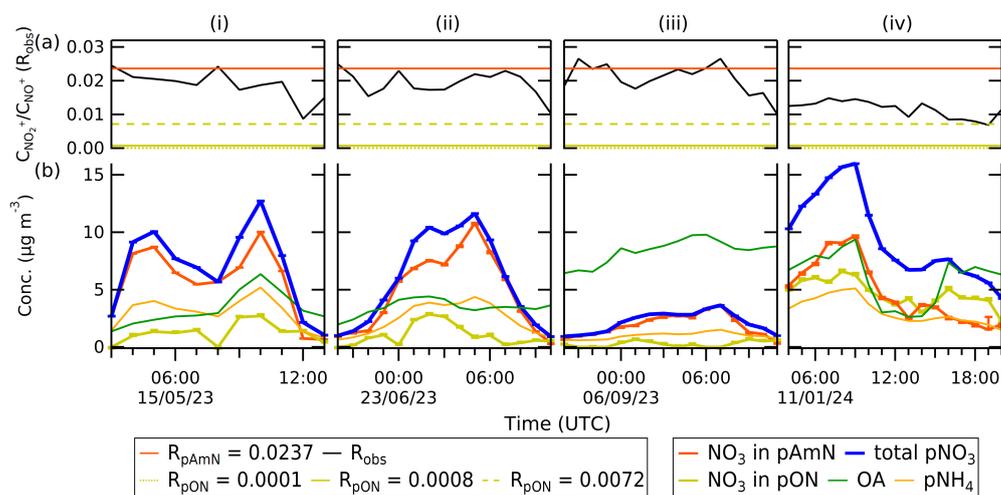

### 355 6.1 Trend of $f_{\text{pON}}$ and $f_{\text{pAmN}}$ vs. ACSM Org and $\text{NH}_4$ at rural site

In order to demonstrate the efficacy of this method, we investigate the trend of  $f_{\text{pON}}$  and  $f_{\text{pAmN}}$  in the dataset observed at Cabauw. The ambient concentration time series of pAmN and pON (using  $R_{\text{pAmN}} = 0.0237$  and  $R_{\text{pON}} = 0.0008$ ) is compared with the ACSM measured Org and  $\text{NH}_4$  fractions, shown in Fig. 5. The time series is averaged to 60 min and filtered using  $R_{\text{pAmN}} = 0.0237$  (values of  $C_{\text{NO}^+} < C_{\text{DL,NO}_2^+} / R_{\text{pAmN}}$  are discarded). We observe that  $f_{\text{pON}}$  is proportional to the fraction of  
360 organic aerosol concentration in total ACSM  $\text{PM}_{2.5}$  ( $C_{\text{OA}} / C_{\text{PM}_{2.5}}$ , from 48% to 64%), whereas the  $f_{\text{pAmN}}$  is proportional to the fraction of particulate ammonium concentration in total ACSM  $\text{PM}_{2.5}$  ( $C_{\text{pNH}_4} / C_{\text{PM}_{2.5}}$ , from 8% to 15%). This shows that the organic nitrate fraction is correlated with availability of organics (particularly at high organics fraction), while the inorganic fraction increases with available  $\text{NH}_4$  (particularly at low ammonium fraction).

We also investigate specific nitrate episodes to show the composition of pON and pAmN in ambient pollution events. The  
365 time series of the  $\text{NO}_x^+$  ratios, ACSM species concentrations (OA,  $\text{pNH}_4$ ,  $\text{pNO}_3$ ), pAmN and pON concentrations are shown in Fig. 6. Four nitrate episodes from spring (15 May 2023), summer (23 June 2023), autumn (05-06 September 2023), and winter (11 January 2024) are shown. The uncertainty of the concentration is obtained by combining the uncertainty from the nitrate fraction ( $f_{\text{pON}}$  or  $f_{\text{pAmN}}$ ), the total ACSM  $\text{NO}_3$ , and the  $R_{\text{pON}}$  value range (see Eqs. S14 and S15). Note that the reported uncertainties are only related to precision uncertainty, and not to concentration quantification (e.g., ionization efficiency) like  
370 the one described by Bahreini et al. (2009) (see details in Section S4.3 of SI). We observe that the adapted  $\text{NO}_x^+$  ratio method is able to separate contributions of pON and pAmN to the total  $p\text{NO}_3$  concentration. In Fig. 6i,ii,iv, we can see that the time series of pON tracks with total OA, while pAmN tracks with  $\text{pNH}_4$  in the rural site. In Fig. 6iii, no significant trend is observed for pON due to lower mass loading of  $p\text{NO}_3$ .

**Figure 5.** (a) The chemical coordinate plot (quantile average) of  $f_{pON}$  against  $C_{OA}/C_{PM_{2.5}}$  shows an average increase of  $f_{pON}$  as OA fraction increases from 48% to 64%, where the  $f_{pON}$  varies from 33% to 66%. (b) The chemical coordinate plot (quantile average) of  $f_{pAmN}$  against  $C_{pNH_4}/C_{PM_{2.5}}$  shows an average increase of  $f_{pAmN}$  as  $pNH_4$  fraction increases from 8% to 15%, where the  $f_{pAmN}$  varies from 30% to 74%. Note: All quantile averages were calculated using the 60 min averaging of the time series. The colored shading is the standard deviation of each quantile average, while the whiskers represent the standard error. They include the uncertainties of ion counting statistics from measurements, uncertainty from ODR fit slope of fragmentation table correction, and  $R_{pON}$  range value.

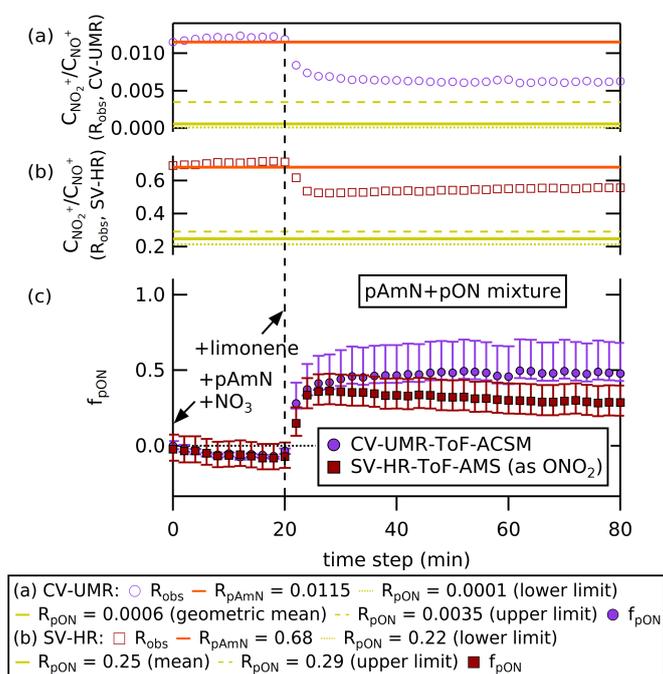

**Figure 6.** The time series for select periods of (a)  $R_{obs}$ , with horizontal lines indicating the values for  $R_{pAmN}$  and  $R_{pON}$ , (b) mass concentration of ACSM-measured total OA,  $pNH_4$ , and  $pNO_3$ , and pAmN and in pON. The separation of pAmN and pON is calculated using  $R_{pAmN} = 0.0237$  and  $R_{pON} = 0.0008$ . The whiskers represent the uncertainty from nitrate fraction ( $f_{pON}$  or  $f_{pAmN}$ ), precision uncertainty of total ACSM  $NO_3$  from Tofware v3.3, and the  $R_{pON}$  value range. The time series (i), (ii), (iii), (iv) represents representative composition in spring, summer, autumn, and winter, all in 60 min time averaging.

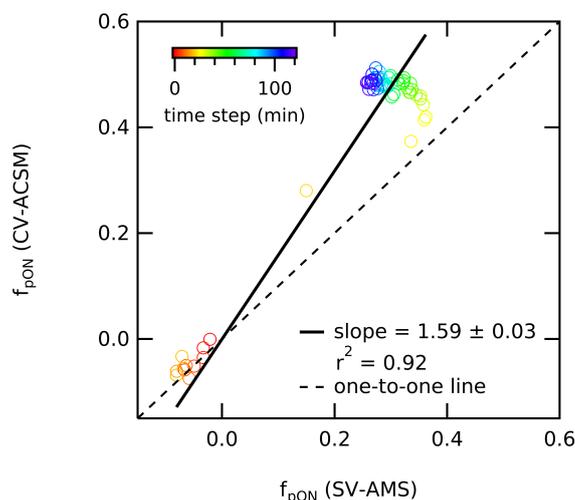

## 6.2 pAmN and pON formation in chamber experiment

375 We investigated the pAmN and pON formation in a chamber experiment using limonene precursor,  $\text{NO}_3$  oxidant, and with  
 AmN seed aerosol. The experiment was carried out in the AIDA chamber. Alongside CV-UMR-ToF-ACSM (ACSM-RUG), a  
 SV-HR-ToF-AMS managed by IMK KIT was also deployed.

The ACSM data is analyzed using the revised fragmentation table specific for terpene chamber experiments (see Section 3.2),  
 while the AMS data is analyzed using Squirrel 1.66E and PIKA 1.26E with the default ion list. Although the time resolution  
 380 is 2 min, time averaging and data filtering is not necessary since the experiment involves high concentrations. The lower  
 limit, geometric mean, and upper limit of  $R_{\text{pON}}$  ( $R_{\text{pON}} = 0.0001; 0.0006; 0.0035$ , respectively) are employed to estimate the  
 uncertainty of  $f_{\text{pON}}$ , alongside  $R_{\text{pAmN}} = 0.0115$  (see Table 2). For the AMS instrument, the measurements of pure pAmN give  
 $R_{\text{pAmN}} = 0.68 \pm 0.05$  and the  $R_{\text{pON}}$  value is calculated using  $RoR = 2.75 \pm 0.41$  Day et al. (2022a), which gives  $R_{\text{pON}} = 0.22$ ;  
 0.25; 0.29 as lower limit, mean, and upper limit, respectively.

**Figure 7.** (a,b) The time series of  $R_{\text{obs}}$ ,  $R_{\text{pAmN}}$ , and  $R_{\text{pON}}$  measured by CV-UMR-ToF-ACSM (top) and SV-HR-ToF-AMS (middle). The fragmentation table specific for glyoxal is used to obtain the  $C_{\text{NO}^+}$  and  $C_{\text{NO}_2^+}$  of the chamber experiment. (c) The time series in 2 min resolution of  $f_{\text{pON}}$  from SV-HR-ToF-AMS and CV-UMR-ToF-ACSM. The markers represent geometric mean for CV-UMR-ToF-ACSM (circle) and mean for SV-HR-ToF-AMS (square). The whiskers represent the uncertainties from the value range of  $R_{\text{pON}}$  combined with the uncertainties from electronic noise, ion counting statistics, fragmentation table (for UMR), and  $R_{\text{pAmN}}$ .

**Figure 8.** Plot of  $f_{\text{pON}}$  from CV-ACSM (y-axis) against  $f_{\text{pON}}$  from SV-AMS (x-axis) using ODR fit. The color scale represents the time step of the experiment in the chamber. The fit shows a good correlation ( $r^2 = 0.92$ ). It also suggests that the  $\text{NO}_x^+$  ratio method applied to CV-UMR-ToF-ACSM reports  $\sim 1.6$  times higher value than SV-HR-ToF-AMS (including correction from Takeuchi et al. (2024)).

385 The  $\text{NO}_x^+$  ratio and  $f_{\text{pON}}$  time series for the limonene SOA experiment are shown in Fig. 7. The whiskers around the mean  
 $f_{\text{pON}}$  represents the uncertainties coming from the value range of  $R_{\text{pON}}$  combined with the uncertainties from ion counting  
statistics, electronic noise, fragmentation table (for UMR), and  $R_{\text{pAmN}}$  (see Section 5.3). The initial mixture of  $\text{NH}_4\text{NO}_3$  seed  
and  $\text{NO}_3$  radical from  $\text{NO}_2$  and  $\text{O}_3$  gives a ratio that matches  $R_{\text{pAmN}}$  from an offline calibration, where  $f_{\text{pON}}$  is close to zero for  
both instruments. After the limonene injection, the  $R_{\text{obs}}$  rose to values in between  $R_{\text{pAmN}}$  and  $R_{\text{pON}}$ , indicating the formation  
390 of a mixture of pAmN and pON inside the chamber.

Based on observations of Takeuchi et al. (2024), pON measured with the SV-AMS is only quantitatively detected as  $-\text{NO}_2$   
moiety, not  $-\text{ONO}_2$ . The reasoning for this difference in detection of  $\text{RONO}_2$  and  $\text{NH}_4\text{NO}_3$  is thought to be due to thermal  
decomposition of pON producing  $\text{NO}_2$  gas in the vaporizer, while  $\text{NH}_4\text{NO}_3$  would more likely decompose to  $\text{HNO}_3$ , and thus  
dominantly ionizing gases of different molecular weights. The “missing oxygen” is generally retained bound to the carbon, and  
395 thus accounted as organic moiety. Thus,  $f_{\text{pON}}$  needs to be corrected for this phenomenon using molar mass ratio of  $\text{NO}_3/\text{NO}_2$   
( $62 \text{ g mol}^{-1}/46 \text{ g mol}^{-1}$ ) to recalculate the pON mass. For the SV-AMS, pON represents  $\sim 32\%$  of the nitrate mixture when  
reported as  $-\text{ONO}_2$ . Without that correction, the measured pON would be underestimated. For the CV,  $f_{\text{pON}}$  represents on  
average  $\sim 50\%$  of the total p $\text{NO}_3$  concentration, higher than the SV (ODR fit slope CV/SV = 1.59,  $r^2 = 0.92$ ; see Fig. 8). There  
is no study yet assessing the necessity of correcting  $f_{\text{pON}}$  in CV, and we suggest that it is likely unnecessary due to the more  
400 complete thermal decomposition that shifts the fragmentation pattern of both  $\text{NH}_4\text{NO}_3$  and  $\text{RONO}_2$  to  $\text{NO}_2$  and  $\text{NO}$ .

Both SV-AMS and CV-ACSM show a similar response to the injection of limonene, whereupon  $f_{\text{pON}}$  increases rapidly from  
0 to  $\sim 0.5$ . The agreement between the two instruments on this initial pON production is encouraging. However, after this  
initial jump, the  $f_{\text{pON}}$  of CV-ACSM remains steady, while the SV-AMS shows gradually decreasing  $f_{\text{pON}}$ . This suggests that

changing contributions of organics at  $m/z$  30 and  $m/z$  46 that may be taken into account by HR peak fitting but not by the  
 405 UMR fragmentation table causes a divergence as the chamber aerosol dilutes. Further investigation of the detailed response of  
 each instrument to changing aerosol composition is needed to resolve this discrepancy. Nevertheless, we are encouraged by the  
 match in responses upon formation of organic nitrate, indicating that the  $\text{NO}_x^+$  ratio method is similarly sensitive to changing  
 nitrate speciation in both instruments.

## 7 Conclusions and recommendations

410 We have successfully shown the separation of particulate ammonium nitrate (pAmN) and particulate organic nitrate (pON) sig-  
 nal from total particulate nitrate (p $\text{NO}_3$ ) signal measured using time-of-flight aerosol chemical speciation monitoring equipped  
 with capture vaporizer in unit mass resolution (CV-UMR-ToF-ACSM), using an adapted  $\text{NO}_x^+$  ratio method with a revised  
 fragmentation table and data pre-treatment. The shift of fragmentation pattern towards smaller ion fragments in the capture  
 vaporizer (CV) compared to the standard vaporizer (SV) affects the signals of  $\text{NO}^+$  and  $\text{NO}_2^+$  fragments and interferences by  
 415 Org fragments used to calculate the  $\text{NO}_x^+$  ratio in UMR. Therefore, we recommend updating the default fragmentation table  
 from Allan et al. (2004) for entries shown in Table 4 before applying the  $\text{NO}_x^+$  ratio method, according to the aerosol composi-  
 tion. As noted previously, substantial corrections to the fragmentation table for these terms have been shown to be needed for  
 measurements using the SV under some conditions (Fry et al., 2018).

**Table 4.** Proposed  $m/z$  30 and 46 entries for Org and  $\text{NO}_3$  in the revised fragmentation table adapted for  $\text{NO}_x^+$  ratio method in CV-UMR-  
 ToF-ACSM. The multipliers ( $a_{\text{Org}[x],[i]}$ ) are applied according to the aerosol composition. The entries that are not included in this table should  
 follow the fragmentation table of Allan et al. (2004) for AMS and adapted without gas-phase corrections (frag<sub>air</sub>) for ACSM.

$m/z$	Revised fragmentation table for CV-UMR-ToF-ACSM		$a_{\text{Org}[x],[i]}$			
	Org	$\text{NO}_3$	General	Biogenic <sup>(a)</sup>	Glyoxal	Terpene
30	$a_{\text{Org}[30],[29]} * \text{frag\_Org}[29]$	[30], -frag <sub>Org</sub> [30]	0.311	0.32	0.291	0.476
46	$a_{\text{Org}[46],[45]} * \text{frag\_Org}[45]$	[46], -frag <sub>Org</sub> [46]	0.305	0.68	0.082	0.204

<sup>(a)</sup>Retrieved from Hu et al. (2017).

The shift of fragmentation pattern in the CV towards more formation of  $\text{NO}^+$  fragments and less of  $\text{NO}_2^+$  fragments changes  
 420 the magnitude of the  $\text{NO}_x^+$  ratio for both pure pAmN and pure pON. The  $\text{NO}_x^+$  ratio in CV is affected by the aerodynamic lens  
 alignment, and therefore we recommend users to align their aerodynamic lens to obtain the correct  $\text{NO}_x^+$  ratio.

To separate the pAmN and pON signal from total p $\text{NO}_3$  and calculate the particulate organic nitrate fraction ( $f_{\text{pON}}$ ), the  
 regular ammonium nitrate calibration should be used to obtain the  $\text{NO}_x^+$  ratio for pure ammonium nitrate ( $R_{\text{pAmN}}$ ), where a  
 value of 0.01-0.07 is expected. On the other hand, we observed from a chamber experiment that the  $R_{\text{pON}}$  value approaches  
 425 zero in the CV. Therefore, we recommend analyzing using three  $R_{\text{pON}}$  values, to describe the upper limit ( $R_{\text{pON}}$  calculated  
 using  $RoR = 3.29$ ), geometric mean, and lower limit ( $R_{\text{pON}} = 0.0001$ ), which also provides  $f_{\text{pON}}$  uncertainty. If possible,  
 we recommend constraining the  $RoR$  for more accurate results (e.g., performing chamber experiment to form pure organic

nitrate). Through this study, we hope to inspire more research regarding  $R_{\text{pON}}$  measurement in CV-based instruments to obtain more precision in analyzing organic nitrate concentrations.

430 The observed  $\text{NO}_x^+$  ratio ( $R_{\text{obs}}$ ) tends to have more noise in CV-based measurements compared to SV. Data filtering using the instrument's  $R_{\text{pAmN}}$  and  $\text{NO}_2^+$  detection limit has shown that the adapted  $\text{NO}_x^+$  ratio method in the CV-UMR-ToF-ACSM is reliable for analyzing pollution episodes with a lower total nitrate concentration limit ranging from 0.6 to 2.0  $\mu\text{g m}^{-3}$ , depending on time averaging. The data pre-treatment is found to filter data points with high fraction uncertainty (above  $\pm 0.5$ ) and decrease the average uncertainty by  $\sqrt{N}$  for each  $N$ -fold of averaging from 10 min. Therefore, time averaging can be  
435 performed to improve the detection limit and decrease the nitrate concentration limit reliable for determination of  $f_{\text{pON}}$  and  $f_{\text{pAmN}}$ . We recommend users to average the time series to 30 min or 60 min to retain information about real ambient variation, while improving the reliable nitrate concentration limit. This may also be convenient when comparing to auxiliary data that are typically reported half-hourly or hourly. In studies where noise is not a problem (e.g., chamber experiments with high particle concentration), time averaging may be unnecessary. With a similar approach, this method can be used for SV-UMR-ToF-ACSM  
440 observations as well, with a fragmentation table suited for SV-based measurements. The adapted  $\text{NO}_x^+$  ratio method on rural nitrate episodes can distinguish periods with pAmN or pON as the major component, confirmed by relation to the ammonium and organic aerosol composition, respectively. Co-located high-resolution time-of-flight aerosol mass spectrometry equipped with standard vaporizer (SV-HR-ToF-AMS) and  $R_{\text{OR}}$  to determine  $R_{\text{pON}}$  in a chamber experiment shows a good correlation ( $r^2 = 0.92$ ) of  $f_{\text{pON}}$  with CV-UMR-ToF-ACSM observation, with the latter estimating  $\sim 1.6$  times higher fraction than the  
445 former. The adapted  $\text{NO}_x^+$  ratio method for CV-UMR-ToF-ACSM demonstrated in this study can be used at monitoring sites to monitor regional  $f_{\text{pON}}$  and improve understanding of particulate nitrate sources and evolution.

*Data availability.* The CV-HR-ToF spectra used to build the revised fragmentation table are retrieved from the open access AMS spectral database ([http://cires1.colorado.edu/jimenez-group/AMSSd\\_CV](http://cires1.colorado.edu/jimenez-group/AMSSd_CV), last access: 6 November 2024). The CV-UMR-ToF-ACSM dataset were collected as part of the Ruisdael Observatory network monitoring (<https://ruisdael-observatory.nl>, last access: 6 November 2024) and are avail-  
450 able upon request. The chamber experiment measurements using SV-HR-ToF-AMS and CV-UMR-ToF-ACSM (ACSM-RUG) were collected as part of the Cloud-Aerosol Interactions in a Nitrogen-dominated Atmosphere (CAINA) project (<https://sites.google.com/view/cainaproject/>, last access: 6 November 2024) in the Aerosol Interaction and Dynamics in the Atmosphere (AIDA) chamber managed by the Institute of Meteorology and Climate Research (IMK) in Karlsruhe Institute of Technology (KIT), Germany.
