Abstract. This paper introduces the [new](#) Ocean Derived Column Optical Depth (ODCOD) algorithm. ODCOD is now being used to retrieve [column optical depths from the 532 nm measurements acquired](#) by the Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP) onboard the Cloud-Aerosol Lidar Infrared Pathfinder Satellite Observations (CALIPSO) spacecraft. ODCOD [retrieves total column optical depths using](#) the lidar [backscatter signal return](#) from the ocean surface, together with collocated wind speed estimates from Modern-Era Retrospective analysis for Research and Applications, Version 2 (MERRA-2). [An advantage of ODCOD retrievals is that the column optical depths include contributions from particulates throughout the entire column including regions with attenuated backscatter below the CALIOP layer detection thresholds. In contrast, the standard CALIOP processing only estimates optical depths for clouds and aerosols detected by the CALIOP layer detection scheme. In this paper we describe](#) the ODCOD algorithm, [develop](#) uncertainty estimates, and [characterize the ODCOD retrievals relative to existing](#) datasets. [The paper presents detailed comparisons of ODCOD retrievals to collocated measurements from Langley Research Center's airborne high spectral resolution lidars \(HSRL\), daytime estimates derived from Moderate Resolution Imaging Spectroradiometer \(MODIS\), and daytime and nighttime optical depths estimates from the Synergized Optical Depth of Aerosols \(SODA\) algorithm. ODCOD aerosol-only optical depth estimates are higher compared to airborne HSRL measurements by \$0.009 \pm 0.043\$ \(median \$\pm\$ median absolute deviation\) or \$6\% \pm 27\%\$ relative difference, lower than MODIS by \$-0.009 \pm 0.041\$ \(\$8.0\% \pm 34\%\$ relative difference\), higher in the daytime than SODA by \$0.004 \pm 0.035\$ \(\$12\% \pm 34\%\$ relative difference\), and higher in the nighttime by \$0.027 \pm 0.034\$ \(\$20\% \pm 33\%\$ relative difference\). In addition to being a new method of retrieving column optical depth, ODCOD's estimates are independent from the standard CALIOP optical depth retrieval algorithms and have potential for further advances in the CALIPSO data record, both to validate CALIOP estimates and as a potential column constraint for future improvements to extinction retrievals.](#)

1 Introduction

The Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP) (Hunt et al., 2009) aboard the Cloud-Aerosol Lidar Infrared Pathfinder Satellite Observations (CALIPSO) spacecraft (Winker et al., 2010) acquired over 17 years of near continuous observations beginning in [mid-June of 2006](#) and [concluded August 1st, 2023](#). CALIPSO's 98.2° orbit inclination yielded near global coverage, allowing for measurements of the location, extent, and optical properties of clouds and aerosols from 82° S to 82° N. CALIOP transmits linearly polarized laser light at 1064 nm and 532 nm, with detectors for the total backscattered signal at 1064 nm and both the parallel and perpendicular polarizations of the backscatter at 532 nm (Hunt et al., 2009). The calibrated perpendicular and parallel signals are summed to retrieve the total attenuated backscatter at 532 nm, and volume depolarization ratios are obtained by dividing the perpendicular signals by the parallel signals (Powell et al., 2009). The science data products retrieved from the CALIOP measurements are reported at three standard processing levels (Vaughan et al., 2023). Level 1 products report calibrated profiles of attenuated backscatter coefficients for all three measurement channels, along with instrument state parameters (e.g., [laser energies](#) and calibration coefficients) and relevant ancillary data such as profiles of atmospheric temperature and pressure. Level 2 products report geophysical parameters

derived from the level 1 calibrated measurements (Winker et al., 2009). These parameters include layer top and base altitudes for all atmospheric and surface features detected in the backscatter profiles (Vaughan et al., 2009) and the identification of atmospheric layers according to type and subtype (Liu et al., 2019; Kim et al., 2018; Avery et al., 2020); and layer optical properties such as optical depths and vertically resolved profiles of particulate extinction and backscatter coefficients (Young et al., 2018). Level 3 products report monthly averages of level 2 retrievals composited on uniform spatial grids (Tackett et al., 2018; Kar et al., 2019, Winker et al., 2023).

This paper describes a newly implemented algorithm for estimating the total column optical depth from the lidar attenuated backscatter return from the ocean surface within the CALIOP suite of algorithms that provide the level 2 data products. This new algorithm is called the Ocean Derived Column Optical Depths or ODCOD algorithm. ODCOD is developed from the work of Venkata and Reagan (2016; hereafter, VR2016) and stands on the legacy of other works that have highlighted the potential of lidar measurements of the ocean surface. In Reagan and Zielinski's 1991 paper, they recognized that they could use "the strong return signals from ground/sea reflections to improve upon information that can be retrieved from spaceborne lidar observations" (Reagan and Zielinski, 1991). Several studies have shown the link between surface wind speed, wave slope variance, and sea surface directional reflectance (Menzies et al., 1998; Lancaster et al., 2005; Hu et al., 2008). Josset et al. (2008) developed the innovative, multi-sensor Synergized Optical Depth of Aerosols (SODA) algorithm that combines ocean surface measurements from CloudSat and CALIOP with Advanced Microwave Scanning Radiometer (AMSR) wind speed retrievals to estimate column optical depths of clouds and aerosols. In contrast, ODCOD derives estimates of column optical depth based solely on CALIOP measurements augmented by wind speeds obtained from Modern-Era Retrospective analysis for Research and Applications, Version 2 (MERRA-2) reanalysis data (Gelaro et al., 2017). Beginning with the Version 4.51 (V4.51) release of the Lidar Level 2 (LL2) CALIPSO data products, ODCOD retrievals of 532 nm total column optical depths are reported wherever a qualified ocean return signal is available.

In the remainder of the paper, we provide a comprehensive overview of the ODCOD retrieval. Section 2 reviews the theory underpinning the algorithm, describes the necessary inputs, the associated profile selection process, and develops uncertainty estimates. Section 3 characterizes ODCOD's performance by making comparisons to collocated airborne high spectral resolution lidar (HSRL) measurements and to the aerosol optical depths (AODs) reported by the Moderate Resolution Imaging Spectroradiometer (MODIS) and SODA data sets. In Sect. 4 we discuss strategies for utilizing ODCOD to improve the standard CALIOP extinction and optical depth retrievals. In closing, Sect. 5 summarizes the advances made by the ODCOD algorithm and provides some concluding remarks.

2 Ocean Derived Column Optical Depth Technique

In this section we describe the details of the ODCOD technique, the required inputs, associated uncertainties, and the contents of the new ODCOD data sets reported in the CALIOP V4.51 LL2 data products.

2.1 Description of Ocean Derived Column Optical Depth Technique

The ODCOD algorithm estimates the attenuation of laser light through the Earth's atmosphere by comparing the magnitude of the attenuated backscatter return from the ocean surface to an unattenuated modelled surface return. The difference between the measured and modelled return is then used to estimate the atmosphere's two-way transmittance from which an estimate of the atmosphere's optical depth is derived. ODCOD starts by fitting the profile of attenuated backscatter measured from the ocean surface to a model of the receiver's impulse response function (IRF) output of a lidar laser pulse. Mathematically, this idealized impulse response model (IRM) is shifted in time (i.e., vertically within the atmospheric column) and then scaled in magnitude to achieve the best fit to the CALIOP surface backscatter measurements. Next, an ideal unattenuated model of the ocean surface backscatter is calculated. The particulate two-way transmittance of the atmospheric column above the surface is then derived from the ratio of the integrals (i.e., areas) of the shifted and scaled IRM and the unattenuated ocean surface backscatter model.

When CALIOP's receiver records a backscatter signal from a hard target such as Earth's surface, the returned signal is a large sudden pulse of photons. The lidar's onboard post-detector electronics employ a third-order low-pass Bessel filter. This filter is downstream of the detectors at both 532 and 1064 nm (VR2016). An important feature of the Bessel low-pass filter is that it preserves the total energy of an incoming pulse. When a large, narrow pulse enters this filter, its peak amplitude is reduced but the pulse is transformed in the time domain such that the area under the original narrow pulse is preserved. The output of the filter can be characterized by its IRF which describes the output signal when the input signal is an impulse, also known as a delta function. When passed through the onboard low-pass filter, backscattered light from CALIOP's laser pulse produces the low-pass filter IRF. Due to the Bessel filter and IRF effect, hard target returns are spread over multiple adjacent CALIOP range bins.

CALIOP employs onboard averaging to reduce data storage and downlink size (Hunt et al., 2009). Onboard the satellite, profile data is sampled into bins at 10 MHz or every 0.1 μ s, corresponding to a vertical sampling resolution of 15 m. At 532 nm, the 10 MHz samples acquired between 8.2 km above mean sea level and 0.5 km below are averaged over two vertical bins, yielding a downlink resolution of 30 m. Consequently, even with the filter broadening effect of the IRF, the entire ocean return signal is contained in only three to four downlinked 30 m range bins at 532 nm. These few range bins contain the information about the attenuation overhead in the magnitude of the signal reaching the surface.

To characterize CALIOP's IRF, CALIOP instrument engineers conducted laboratory experiments prior to launch in which short, high intensity pulses of laser light were measured using the CALIPSO engineering model receiver electronics and flight-qualified photomultipliers. Since the original model parameters were not published in VR2016, we developed an analytic model of the IRF using the concepts they outlined. We fit digitizer readings from the engineering model receiver electronics to a hyperbolic tangent for the rising part and a Gaussian curve for the falling part. Figure 1 shows a typical example, where the digitizer readings for the impulse response (purple diamonds) are shown plotted as a function of elapsed time from the pulse onset. The analytic model is set to zero for all times prior to the pulse onset.

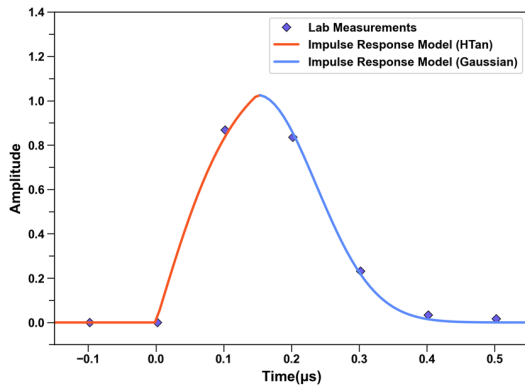

Figure 1: The CALIOP IRM derived from laboratory measurements. The purple diamonds show lab measurements taken at intervals of 0.1 μs, while the red and blue solid lines show the analytic curve fit to the rising signal prior to the peak and the decaying signal following the peak, respectively.

VR2016 found that a similar approximation falls within 1 % of expected 3rd order Bessel function IRFs and has similar characteristics to the CALIOP filter. Because the lidar laser pulse was used to create the IRM, rather than a true delta function, the IRM is theoretically a closer approximation to a CALIOP hard target return than using a pure delta function impulse response output. The IRM is used to estimate the magnitude of CALIOP's surface return.

The magnitude of the surface return has a direct relationship to the total two-way transmittance. VR2016 relate the area under the IRM to the total two-way transmittance with Eq. (1):

$$A_{IRM} = \frac{2T^2(z_s)R_\lambda(\omega, \theta)}{c}$$

In this expression, A_{IRM} is the area under the IRM where R_λ is the ocean surface retro or backscatter reflectance which is a function of the wind speed at 10 m above the ocean surface (ω) and the off-nadir angle of the spacecraft (θ), and c is the speed of light. $T^2(z_s)$ is the total two-way transmittance of the atmosphere at the ocean surface, which is the product of the molecular and ozone two-way transmittances ($T_M^2(z)$), and the particulate two-way transmittance ($T_P^2(z)$). Rearranging this equation yields an expression for the two-way transmission due to particulates alone, as shown in Eq. (2). This is the governing equation for ODCOD, from which optical depths are retrieved.

$$T_P^2(z_s) = \frac{cA_{IRM}}{2R_\lambda(\omega, \theta)T_M^2(z_s)} \quad (2)$$

As in standard CALIPSO processing, $T_M^2(z_s)$ is estimated from molecular and ozone number densities obtained from the MERRA-2 model (Kar et al., 2018). VR2016 relate R_λ to wind speed using a revised and updated version of the ocean surface backscatter reflectance model developed by Lancaster et al. (2005) using Eq. (3):

$$R_\lambda(\omega, \theta) = (1 - W(\omega))F_\lambda(\omega, \theta) + 0.2W(\omega) \quad (3)$$

where W is the fraction of the surface covered with whitecaps, F_λ is the Fresnel retro reflectance of ocean water, and the factor of 0.2 is the estimated Fresnel retro reflectance of ocean whitecaps. The whitecap fraction W is estimated by Eq. (4):

$$W(\omega) = 2.95 \times 10^{-6} (\omega)^{3.37} \quad (4)$$

The whitecap fraction model used by ODCOD is the empirical fit found in Lancaster et al. (2005) but with updated coefficients provided by VR2016. The ocean surface backscatter reflectance model is comprised of an ocean water component and a white cap component. As wind speeds increase, the fraction of the total ocean surface backscatter reflectance attributed to white caps increases significantly. Furthermore, the magnitude of F_λ varies as a function of off-nadir angle, which is relevant for CALIOP calculations. At launch, the CALIPSO off-nadir angle was fixed at 0.3°. However, the off-nadir angle was increased to 3.0° in November 2007 (Winker et al., 2009) and 3.0° continued as the nominal off-nadir angle until the end of the mission. In Eq. (5), we adopt the estimate of F_λ as a function of wind speed and off-nadir angle from Josset et al. (2010b):

$$F_\lambda(\omega, \theta) = \frac{\xi_\lambda e^{-\frac{\tan^2 \theta}{(s(\omega))^2}}}{4\pi(s(\omega))^2 \cos^5 \theta} \quad (5)$$

Moved (insertion) [5]

Moved (insertion) [6]

960 where ξ_λ is the Fresnel coefficient at wavelength λ , which we estimate as 0.0213 at 532 nm and 0.0202 at 1064 nm
 (Vaughan et al., 2019), and $\langle s(\omega) \rangle^2$ is the wave slope variance which is also a function of wind speed. While VR2016 used
 the wave slope variance approximation proposed in Lancaster et al. (2005), for ODCOD we have chosen to use the
 piecewise approximation developed by Hu et al. (2008). This approximation was developed using CALIOP measurements
 and AMSR wind speeds and directly relates the two primary quantities used in the ODCOD retrieval and is shown in Eq. (6):

965

$$\begin{aligned}
 \omega < 7 \frac{m}{s} & \quad \langle s(\omega) \rangle^2 = 1.46 \times 10^{-2} \sqrt{\omega} \\
 7 \frac{m}{s} \leq \omega < 13.3 \frac{m}{s} & \quad \langle s(\omega) \rangle^2 = 0.003 + 5.12 \times 10^{-3} \omega \\
 13.3 \frac{m}{s} \leq \omega & \quad \langle s(\omega) \rangle^2 = 0.138 \log_{10}(\omega) - 0.084
 \end{aligned} \tag{6}$$

As illustrated in Fig. 1, ODCOD approximates the IRM using the piecewise analytic function given in Eq. (7).

$$f_{IRM}(t_s) = \alpha \times \begin{cases} 0 & \text{for } t_s \leq 0.0\mu s \\ a_h \tanh(\omega_h t_s) & \text{for } 0.0\mu s < t_s \leq b_p \\ a_g e^{-(\omega_g |t_s - g|)} & \text{for } t_s > b_p \end{cases} \tag{7}$$

970 Integrating this function yields the requisite A_{IRM} estimates. Table 1 shows the parameters which define the ODCOD IRM
 and were selected to fit the lab measurements.

Deleted: CALIOP

The first step in fitting the IRM to the measured ocean surface attenuated backscatter signal is to find the sample time delay, t_s . The sample time delay is the temporal offset between the actual ocean surface signal onset and the midpoint of the CALIOP onboard or downlinked sample range bin. Because the time delay is not a function of the IRM, there is not a unique IRM value for every time delay within the surface pulse. Instead, the ratio of two consecutive samples is used which does have a unique value for any time delay within the surface return.

By using the ratio of two points, the scale factor term α cancels out and we can use an unscaled IRM to find two samples that match the ratio of two known points. However, we don't know the magnitude of the original onboard samples and instead only know the downlinked samples. The ratio of two consecutive downlinked samples can also be used in the same way but we must create a mapping of the IRM to an onboard averaged IRM. Equation (8) shows the relationship of the IRM to the downlinked samples and can be thought of as a downlinked IRM (DIRM).

$$f_{DIRM}(t_s) = \frac{(f_{IRM}(t_s - 0.05 \mu s) + f_{IRM}(t_s + 0.05 \mu s))}{2} \quad (8)$$

By using the downlinked samples and because the downlinked sample ratio is a function of the IRM, the scale factor still cancels, and we can then find the time delay of the original onboard samples. To do this, we use a simple bisecting search algorithm. Figure 2 shows how the IRM, DIRM, and the ratio of two consecutive DIRM samples are all connected by the sample time delay. The annotated aqua circles are the IRM at $t_s - 0.05 \mu s$ and $t_s + 0.05 \mu s$ and are averaged to make the purple diamond of the DIRM at t_s . The time delay of t_s has a unique orange diamond DIRM ratio value. All time delays after the onset of the DIRM have unique values and can be used to solve for the time delay.

Deleted: It is possible to estimate the magnitude of the ocean surface return using ODCOD's CRM because a hard target largely preserves the shape of the laser pulse upon reflection. The reflected pulse is then recorded by the spacecraft receiver having only been two-way attenuated by the atmosphere. The Bessel filters modify the shape but preserve the total backscattered energy of the reflected pulse. After passing through the system electronics, digitized samples of the filter response are recorded. CALIOP's onboard sampling rate is 10 MHz, or every 0.1 μs , corresponding to a vertical sampling resolution of 15 m, which is identical to the sampling rate of the laboratory measurements used to build the CRM. However, because

Moved up [4]: CALIOP employs onboard averaging to reduce data storage and downlink size (Hunt et al.,

Moved up [11]: As illustrated in Fig.

Deleted: 2009), the 532 nm samples acquired between 8.2 km above mean sea level and 0.5 km below are averaged over two onboard vertical bins, yielding a downlink resolution of 30 m. Once averaged, the original onboard samples are discarded leaving only the averaged measurements for analysis.

Ideally, ODCOD would fit the 15 m ocean surface attenuated backscatter measurements to the 15 m resolution CRM, then integrate the piecewise model to retrieve the area under the CRM. Accomplishing this fit would align the surface return measurements to the model and then scale the model to best fit the measurements thus solving for the scale factor (α). Unfortunately, implementing this CRM fitting procedure is considerably complicated by CALIOP's onboard averaging scheme.

Deleted: 2, the average of any two temporally consecutive 0.1 μs points from the CRM (circles lying along the aqua curve) yields a 0.2 μs resolution value (purple diamonds) that does not lie on the CRM. Consequently, applying the fitting procedure described requires a mapping from the CRM into a "downlinked CALIOP response model" (DCRM) that is defined at the same 30 m resolution as the downlinked data. This derivation of the DCRM from the CRM is given in Eq. (4).

$$DCRM(t) = \frac{(CRM(t-0.1 \mu s/2) + CRM(t+0.1 \mu s/2))}{2}$$

Deleted: The DCRM is created by averaging the CRM in the exact same way that the 0.1 μs (15 m) digitized samples are averaged onboard the spacecraft to create the downlinked measurements. As illustrated by the orange line in Fig. 2, an especially useful property of the DCRM is that the ratio of any two temporally consecutive samples taken at the CALIOP downlinked sample spacing is unique. While the CRM and DCRM are continuous functions, any single measurement or sample is one of a discrete set at times t_{s_i} where each t_{s_i} is a function of some reference sample or measurement time t_{s_0} . The relationship of the times is $t_{s_i} = t_{s_0} + iR_s$. Where R_s is the sampling rate and the measurement index i is the number of measurements from the reference measurement at time t_{s_0} . The measurement index may be positive or negative depending on if it falls before or after the reference measurement. Since the DCRM is mapped to the CRM, a sample time of one model also defines the samples on the other. Since the ratio of two consecutive DCRM samples is unique, the time of a selected downlinked reference measurement can be determined from the DCRM without first knowing the DCRM scale factor by ratioing the reference measurement with the following measurement. By locating ... [20]

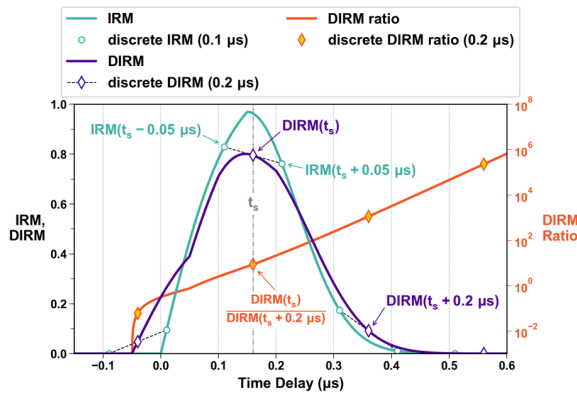

Figure 2: The CALIOP JRM (aqua line) with one possible set of discrete samples (circles) and the resulting $DIRM$ (purple) with the downlinked samples (purple diamonds) that result from the discrete samples of the JRM linked (black dashed line). Overplotted on the right axis is the ratio of the $DIRM$ (orange) at time delay t_s over the $DIRM$ at time delay $t_s + 1$, with the discrete ratios (orange diamonds). Highlighted by the annotations are the JRM , $DIRM$, and $DIRM$ ratio for the specific time delay t_s , annotated and marked by the vertical line to show how all three tie together.

Two adjacent test samples must be selected to take the ratio of and find the time delay. If the CALIOP surface detection algorithm has correctly identified the surface top and base altitudes, at least two vertically adjacent downlinked samples should be part of the surface return signal. In an ideal signal, any measurement that is not part of the surface return would be completely zero and any measurement on or after the surface return onset would be non-zero. However, the measured downlinked samples before the surface return onset are rarely if ever actually zero so it is critical that whatever consecutive sample pair is selected is part of the surface return. To ensure the test samples are part of the surface return, the largest measurement of the suspected surface return and the largest adjacent measurement are chosen as the test samples. These points are assumed to have at least one onboard sample that is part of the surface return due to their magnitude and have the best signal-to-noise ratio which will minimize error in finding the time delay due to noise. If the number of downlinked samples between the CALIOP detected surface top and base exceed four range bins, a surface detection failure is suspected, and no retrieval is attempted.

If a downlinked sample's time delay places it before the onset of the IRM (i.e. a time delay less than zero), that sample may still be part of the surface return as long as one of the averaged onboard samples is part of the surface. A minimum time delay can be calculated for the DIRM as a function of the number of onboard samples averaged and is calculated by $t_{min} = T_s(1 - n)/2$ and $t_{max} = T_s(1 + n)/2$ where T_s is $0.1 \mu s$ and n is the number of samples averaged onboard (i.e. two for

- Deleted: The key takeaway from Fig. 2 is that the ratio of two consecutive DCRM samples is unique irrespective of their magnitude. Furthermore, t_{s0} is a function of that ratio, as are all the t_{s_i} in the surface return. Using the ratio and time relationship as illustrated by the orange curve in Fig. 2, the time of the reference downlinked measurement and thus time of all downlinked measurements in the profile are found. Once the time of the measurements on the DCRM is known, the DCRM can be scaled by α to match the measurement's magnitudes. The CALIOP surface detection algorithm provides the downlinked measurements of attenuated backscatter of the ocean surface. The two largest consecutive measurements of the detected surface return are selected and the first of the two is chosen as the reference measurement. The ratio of these measurements is compared to ratios of sample ... [21]

CALIOP at 532 nm). Based on the derived time delay, we calculate which sample of the surface return the test sample is by adding or subtracting the time between range bins until the time delay falls within t_{min} and t_{max} .

Since the time delay tells us which points of the surface return have been found, if the CALIOP surface detection algorithm is missing points before or after the identified surface measurements, ODCOD will include them to ensure the correct surface points are used. These actions only affect ODCOD and do not attempt to alter CALIOP's reported surface detections.

The scale factor is found by starting with a scale factor of 1×10^{-5} and incrementally increasing this value until the sum of the squared error (SSE) between the measured samples of the surface return and the matching DIRM samples is no longer reduced. Then a bisecting search algorithm is used to find a SSE less than 1×10^{-5} or successive scale factors have a relative difference of less than 1×10^{-5} . The remaining differences in the samples are used to estimate the uncertainty in the area under the IRM.

With the time delay and scale factor determined, the integral of the IRM is simply the integral of the two parts of the unscaled IRM model multiplied by the scale factor, as shown in Eq. (9):

$$A_{IRM} = \alpha \left(a_h \int_{0.6\mu s}^{b_p} \tanh(\omega_h t) dt + a_g \int_{b_p}^{\infty} e^{-(\omega_g(t-g))^2} dt \right) \quad (9)$$

$$\omega < 7 \frac{m}{s}$$

$$13.3 \frac{m}{s} \leq \omega$$

The final pieces of the equation are the off-nadir angle, which is known from the spacecraft attitude data, and the horizontal wind speed magnitude at 10 m above the ocean surface, which is obtained from the MERRA-2 model. We have found however, that the MERRA-2 10 m winds over the ocean are biased low and require a correction to obtain unbiased optical depth estimates. An in-depth discussion of the wind speed bias correction is given in Sect. 2.2.1. These corrected MERRA-2 winds are used in the ODCOD algorithm.

Using the IRM has some advantages over techniques that use the integrated attenuated backscatter of the surface when estimating the area of the surface return. Namely, the IRM does not significantly include contributions from light scattered from below the ocean surface. The 532 nm light is largely extinguished within only a few tens of meters in the ocean (VR2016) but will make a small contribution to the overall return. Significant scattering from below the air-ocean interface would effectively widen the surface pulse but not introduce a uniform enhancement of the measurements. Some subsurface enhancement can occur in the individual measurements as a function of their respective time delays, but that enhancement is

assumed to be less significant than the overall effect. Furthermore, since only the two largest points of the return are used in the fitting process, any enhancement in the tail of the return is immaterial. Any subsurface enhancement of the area under the fit IRM is assumed to be insignificant compared to other uncertainties of the algorithm and at most will cause a small bias in the retrieval.

In addition, using the IRM overcomes possible effects from the non-ideal transient recovery by the 532 nm photomultipliers following very strong backscatter signals (Hunt et al., 2009). As explained by McGill et al. (2007), “following a strong impulse signal, such as from the Earth’s surface or a dense cloud, the signal initially falls off as expected but at some point, begins decaying at a slower rate that is approximately exponential with respect to time.” Because ODCOD only fits the largest points of the surface return, the tail effect phenomenon will not affect the surface return fit. We assume any enhancement from the tail effect in the design of the IRM is insignificant compared to the surface return.

Lastly, by using only information already available in CALIPSO standard processing, ODCOD avoids many of the uncertainties associated with using external measurements from other instruments to attempt a similar retrieval. Note that the ODCOD retrieval can in principle be applied on the CALIOP 1064 nm channel. However, additional accommodations would need to be made to account for the coarser downlink resolution (60 m at 1064 nm versus 30 m at 532 nm). Implementing ODCOD at 1064 nm is currently under investigation by the CALIOP team.

2.2 Algorithm Inputs and Uncertainties

This section examines the necessary inputs to the ODCOD algorithm, their uncertainties, and how those uncertainties affect the uncertainty of the retrieval. Ancillary inputs are also discussed along with their uses in data filtering and quality assurance.

Applying standard propagation of error techniques (Bevington and Robinson, 1992), the estimated variance in the ODCOD two-way transmittance is shown in Eq. (10).

$$\sigma_{T_P^2}^2 = \left(\frac{\delta T_P^2}{\delta \omega}\right)^2 \sigma_{\omega}^2 + \left(\frac{\delta T_P^2}{\delta \theta}\right)^2 \sigma_{\theta}^2 + \left(\frac{\delta T_P^2}{\delta A_{IRM}}\right)^2 \sigma_{A_{IRM}}^2 + \left(\frac{\delta T_P^2}{\delta T_M}\right)^2 \sigma_{T_M}^2 \quad (10)$$

The variance of the off-nadir angle, molecular and ozone two-way transmittances, and the estimate of the Fresnel coefficients are assumed to be insignificant compared to that of wind speed and area fit. We choose to ignore these uncertainties in the ODCOD uncertainty estimate so Eq. (10) simplifies to Eq. (11).

- Deleted:** Another source of systematic error that affects ODCOD retrievals is ocean subsurface scattering. VR2016 show that the 532 nm light is largely extinguished to less than 0.1 % within 45 m below the surface but will make a small contribution to the overall return. Due to the CALIOP onboard electronics system, subsurface scattering will effectively widen the surface pulse but does not introduce a uniform enhancement of the measurements. Some subsurface enhancement will occur in the individual measurements as a function of their respective pulse onset time delays, but fitting only the largest two points of the CRM means the magnitude of any enhancement will vary as a function of time delay. Attempts to correct for subsurface contribution using conventional theoretical corrections as proposed in VR2016 and Josset et al. (2010b) consistently underestimates the IAB, so ODCOD applies no such correction. The failure of the CRM to avoid the subsurface component of the ocean surface return introduces a small systematic error that needs additional study to fully understand and quantify before a correction is attempted.
- Deleted:** Random Uncertainty
- Deleted:** random uncertainty
- Deleted:** estimate
- Deleted:** random
- Deleted:** particulate
- Deleted:** $\left(\frac{\delta T_P^2}{\delta A_{CRM}}\right)^2 \sigma_{A_{CRM}}^2$

$$\sigma_{T_p^2}^2 = \left(\frac{\delta T_p^2}{\delta \omega}\right)^2 \sigma_{\omega}^2 + \left(\frac{\delta T_p^2}{\delta A_{IRM}}\right)^2 \sigma_{A_{IRM}}^2 \quad (11)$$

To isolate the change in the two-way transmittance variance due to wind speed arising from multiple terms, we expand the wind speed term in Eq. (11) as shown in Eq. (12) through (14):

$$\frac{\delta T_p^2}{\delta \omega} = \frac{-c \cdot A_{IRM}}{2 \cdot R_{\lambda}^2 \cdot T_{mol}^2 \cdot T_{\theta_3}^2} \cdot \frac{\delta R_{\lambda}}{\delta \omega} \quad (12)$$

$$\frac{\delta R_{\lambda}}{\delta \omega} = (0.2 - F_{\lambda}) \left(2.95 \times 10^{-6} (3.37) \omega^{2.37} \right) + (1 - W) \frac{\delta F_{\lambda}}{\delta \omega} \quad (13)$$

$$\frac{\delta F_{532}}{\delta \omega} = \xi_{532} \cdot \exp\left(-\frac{\tan^2 \theta}{(S)^2}\right) \cdot \frac{\tan^2 \theta - (S)^2}{4\pi((S)^2)^3 \cos^5 \theta} \cdot \frac{\delta (S)^2}{\delta \omega} \quad (14)$$

The three parts of Eq. (6) relate wind speed to wave slope variance. The change in wave slope variance as a function of wind speed is derived using the three parts of Eq. (15).

$$\begin{aligned} \omega < 7 \frac{m}{s} & \quad \frac{\delta (S)^2}{\delta \omega} = \frac{1.46 \times 10^{-2}}{2\sqrt{\omega}} \\ 7 \frac{m}{s} \leq \omega < 13.3 \frac{m}{s} & \quad \frac{\delta (S)^2}{\delta \omega} = 5.12 \times 10^{-3} \\ 13.3 \frac{m}{s} \leq \omega & \quad \frac{\delta (S)^2}{\delta \omega} = \frac{0.138}{\omega \ln(10)} \end{aligned} \quad (15)$$

The partial derivative of two-way transmittance with respect to area under the JRM is shown in Eq. (16).

$$\frac{\delta T_p^2}{\delta A_{IRM}} = \frac{c}{2R_{\lambda}(\omega, \theta) T_M^2(z_s)} \quad (16)$$

To estimate the variance in the ODCOD two-way transmittance, estimates of the variance in wind speed and area of the shifted and scaled IRM are required and discussed in the next two sections. Finally, the uncertainty in optical depth can be calculated as:

$$\sigma_{\tau} = \sqrt{\frac{\sigma_{T_p^2}^2}{(2T_p^2)^2}} \quad (17)$$

Deleted: The standard deviation of the off-nadir angle is estimated from internal CALIPSO engineering documents as 0.16° making its contribution to the overall uncertainty approximately 0.01 % of the uncertainty overall. Uncertainty in the MERRA-2 model temperature data used to estimate particulate and ozone two-way transmittance for ODCOD are estimated to be less than 1.5 K (M. Rienecker, personal communication, 2013). Even assuming a uniform 4 K error in the MERRA-2 temperature profile, the fractional error in the molecular two-way transmittances is on less than 0.004. Using this as an estimate of the random uncertainty, the contribution to the overall uncertainty should be less than 0.02 %. As these uncertainties are small compared to that of wind speed and area fit, they are not included in the ODCOD uncertainty estimates. Without the contributions of viewing angle and the molecular and ozone two-way transmittances, Eq. (11) simplifies to Eq. (12).[†]

$$\sigma_{T_p^2}^2 = \left(\frac{\delta T_p^2}{\delta \omega}\right)^2 \sigma_{\omega}^2 + \left(\frac{\delta T_p^2}{\delta A_{CRM}}\right)^2 \sigma_{A_{CRM}}^2 \quad \dots [28]$$

If we recall Eq. (6) for the wave slope variance, we know there are two distinct discontinuities in the piecewise function at 7 m s^{-1} and 13.3 m s^{-1} . Due to the discontinuities, there are also discontinuities in the analytical estimation of the uncertainty in the optical depths retrieved by ODCOD, due to Eq. (15) being part of the overall uncertainty estimate. These discontinuities can easily be seen in the 5km ODCOD estimation of standard deviation as calculated by Eq. (17) when binned by wind speed (Fig. 3(a)). This is unfortunate, as the uncertainties for retrievals with wind speed values near the discontinuities will make the uncertainty estimate less certain. Nonetheless, extensive comparisons of ODCOD aerosol-only optical depths to other data sets demonstrate that in general, ODCOD uncertainty estimates provide a reliable estimate of the overall uncertainty in the ODCOD retrieval (Sect. 4).

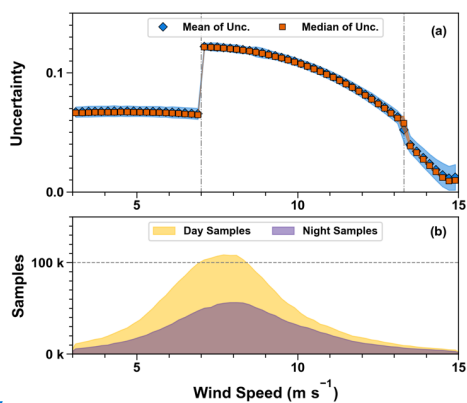

Figure 3: Panel (a) shows ODCOD 5 km AOD standard deviation estimate means (blue diamonds) calculated by Eq. (17) with standard deviation envelope and medians (orange squares) with median absolute deviation (MAD) envelope binned by wind speed. Grey reference lines at 7 and 13.3 m s⁻¹ coincide with the breakpoints in the wave slope variance model in Eq. (6). Panel (b) shows the number of samples for daytime (yellow) and nighttime (purple). Both panels represent the data for March 2008–February 2011.

Deleted: To estimate the variance in the ODCOD particulate two-way transmittance, estimates of the variance in wind speed and area of fitted CRM are required. These are discussed in detail in the next two sections.

Deleted: (10).

Deleted: Because the median of the distribution of optical depths shown in Fig. 3(b) is near the discontinuity at 7 m s^{-1} in Fig. 3(a) the distribution of reported uncertainties will be distinctly bimodal. This reduces the utility of the uncertainties reported because retrievals with wind speed values near the discontinuities will make the uncertainty estimate less certain. Nonetheless, extensive comparisons of ODCOD AODs to other data sets demonstrate that in general, ODCOD uncertainty estimates provide a reliable estimate of the overall random uncertainty in the ODCOD retrieval (Thorsen)

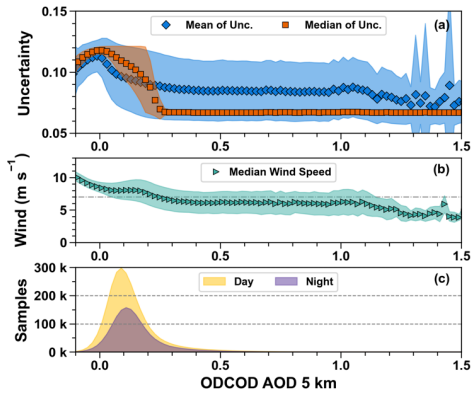

Figure 4: Panel (a) shows ODCOD 5 km AOD standard deviation estimate means (blue diamonds) calculated by Eq. (17) with standard deviation envelope and medians (orange squares) with median absolute deviation (MAD) envelope and binned by ODCOD 5 km AOD. Panel (b) shows the median wind speed with MAD envelope for the same data in Panel (a) with a grey reference line at 7 m s⁻¹. Panel (c) shows the number of samples in daytime (yellow) and nighttime (purple). All panels represent the data for March 2008–February 2011.

To understand the major impacts on AOD uncertainty in Fig. 4(a), we mainly need to consider the wind speeds in these regimes and how they affect the uncertainty overall. The uncertainty due to A_{IRM} only plays a minor role and is mostly responsible for the smaller fluctuations of the values in Fig. 3(a). Figure 4(b) shows that generally, the median wind speeds fall between 5–8 m s⁻¹, with only AOD values below zero and above about 1.1 being much outside the range. The larger wind speeds for AOD below 0 are attributed to the fact that at lower wind speeds, the ocean is more reflective and has a higher chance of saturating the detectors at very low optical depths. Because ODCOD retrievals are not performed for saturated surface returns, the returns that qualify for attempting ODCOD will statistically have higher wind speeds. This surface-saturation sampling bias is discussed in more detail in Sect. 3.1.1. Figure 3(a) shows that uncertainty increases substantially for wind speeds just above the 7 m s⁻¹ threshold as compared to lower wind speeds. This means that for the distribution of wind speeds found in nature, there will be a bimodal distribution of uncertainty values for ODCOD optical depths, with a tight distribution around 0.065 and a wider distribution around the 0.12. The fraction of each distribution in any collection of data binned by AOD will depend on the standard deviation of the wind speeds and how close to the threshold value the wind speed distribution is. It is the bimodal nature of these uncertainties that explain the large features of the ODCOD uncertainty landscape.

We will now analyze a few of the specific largescale features of the uncertainty distribution more closely. Starting on the left of Fig. 4(a), while it only represents a small fraction of the data, the uncertainties of negative AOD retrievals are smaller than

500 AODs near 0. Negative optical depths typically occur due to noise in the surface return measurements of optically thin atmospheric conditions. Noise in the measurements can cause the IRM fit to over or underestimate the surface return but when the surface return is estimated too large and the optical depth is nearly zero, the retrieved estimate can be less than zero. In optically thin atmospheric conditions, the surface return can become bright enough to saturate the detectors and when the wind speed is low, the ocean surface reflectivity is increased which further increases the surface return and exacerbates the saturation. This means successful retrievals at very low optical depths occur preferentially at higher wind speeds. Higher wind speeds are where the contribution of uncertainty due to wind speed is smaller compared to that of lower wind speed values. In Fig. 4(b), we see the wind speed ranges drop from 10 m s⁻¹ down to about 8 m s⁻¹ which aligns on Fig. 3(a) with uncertainty values of less than 0.11 up to 0.12 which is the same as what is shown on Fig. 4(a).

510 The mean and median uncertainties separate for AOD values from 0 to 0.25 because there is a mixture of retrievals with wind speeds above and below the 7 m/s threshold, thereby yielding higher or lower uncertainties. Figure 4(b) shows the wind speed median is about 8 m s⁻¹ but then drops below the 7 m s⁻¹ threshold by 0.25 AOD approaching a constant 6 m s⁻¹. Again, this is consistent with Fig. 3(a) where near the 7 m s⁻¹ threshold the uncertainty is basically chosen from either about 0.12 when the wind speed is above the threshold and about 0.065 when below.

515 Finally, the strong skew and relatively constant mean and standard deviation for AOD greater than 0.25 is because the wind speeds for these retrievals are more often below 7 m s⁻¹. The median being a nearly constant value of 0.065 with a median absolute deviation (MAD) of around 0.001 yet the mean being 0.085 with a standard deviation of about 0.025 is indicative of the strongly bimodal distribution of uncertainties.

520 In the CALIOP data products, ODCOD uncertainties are reported as the optical depth estimated standard deviation derived according to Eq. (17). In general, ODCOD filtered for wind speeds between 3–15 m s⁻¹ has an uncertainty of 0.12 ± 0.05 (76 % ± 40% relative uncertainty). Daytime uncertainty is 0.11 ± 0.01 (79 % ± 45 % relative) and nighttime is 0.11 ± 0.01 (71 % ± 34 % relative). Despite the discontinuities and difficulties in making the estimation, ODCOD's reported standard deviation estimates are a good approximation of the standard deviation in the retrieved optical depth.

2.2.1 Wind Speed

530 Wind speed is the largest source of uncertainty in the ODCOD algorithm; however, MERRA-2 does not provide standard deviation estimates for the wind speeds reported in their product. We have therefore adopted a global wind speed uncertainty based on the available literature. According to Archer and Jacobson (2005), “the global average 10 m wind speed over the ocean from measurements is 6.64 m s⁻¹.” Similarly, Wentz et al. (2005) report a maximum standard deviation of AMSRE,

wind speeds relative to ocean buoy measurements of less than 1.00 m s^{-1} . From these measurements we derive an estimated relative wind speed standard deviation of $\epsilon_{\omega M} = 1.00 \text{ m s}^{-1} / 6.64 \text{ m s}^{-1} \approx 0.151$.

Deleted: An estimate of

Deleted: is derived from these measurements as

In addition to random uncertainties, another issue that must be addressed is potential bias in the MERRA-2 winds at 10 m above the ocean surface. Compared to buoy and other in situ measurements, Carvalho (2019) found a low bias in MERRA-2 winds from -0.16 to -0.83 m s^{-1} over ocean. We also found a similar bias of $-0.52 \pm 0.53 \text{ m s}^{-1}$ (global average) during our development of a correction to mitigate MERRA-2 wind speed biases, detailed below. To demonstrate the significance of a wind speed bias, a low wind speed bias of -0.5 m s^{-1} will cause a high bias of approximately 0.02 in an ODCOD optical depth.

Deleted:).

To develop a wind speed correction, we analyzed the 10 m medium frequency surface wind speed reported by the Advanced Microwave Scanning Radiometer for Earth Observing System (AMSRE) aboard the NASA Aqua Satellite from June 2006 to October 4, 2011, and the Advanced Microwave Scanning Radiometer 2 (AMS2) aboard the Global Change Observation Mission - Water (GCOM-W1) satellite from May 2012 through December 2020. The AMSR data sets were chosen due to the respective spacecraft's approximately 90 s separation from the CALIPSO spacecraft. Their proximity allows for near instantaneous coincident measurements between CALIOP and the AMSR instruments. When comparing the two AMSR instruments, no significant bias was found so we use aggregated AMSRE and AMS2 data to cover nearly the entire CALIPSO mission. These wind speeds were collocated to the 333 m CALIOP footprint and compared to the GMAO MERRA-2 10 m surface wind speeds retrieved from the inst2d_met data parameters and reported the CALIOP LL2 V4.51 data products.

Deleted: assess potential biases in MERRA-2

Deleted: speeds,

Deleted: 10 m

Deleted: speeds

Deleted: were analyzed.

From the median differences calculated, we generated 14 lookup tables consisting of wind speed ranges from 1 m s^{-1} to 41 m s^{-1} in 3 m s^{-1} increments. Each table is a three-dimensional 164 by 180 by 12 lookup table comprised of one-degree latitudes from 82° S to 82° N , two-degree longitudes, and month of the year for the respective wind speed range. We calculated the median wind speed differences between the AMSR instruments, and the MERRA-2 reported wind speeds for each month. To interpolate a wind speed bias correction for any wind speed, latitude, longitude, and time, we required each grid box in the lookup table to have a minimum of five observations to average. If enough data was not available for any given grid box, we re-binned the data onto larger-sized grids until the minimum data requirement was met, and then populated all the fine grid boxes with the coarser grid value to fill in the map. This technique allows the wind speed bias values, which are only available over ocean, to be populated over land. Over land values are rarely, if ever, used and then only on those occasions where ODCOD is attempting a retrieval very near shore. This bias correction produces a more AMSR-like wind estimate.

Deleted: AMSR data from June 2006 to October 4, 2011, and AMSR2 data from May 2012 through December 2020 were used. The AMSRE and AMSR2 instruments are very similar in design and no bias between their wind speed estimates was noted by a search of the available literature at the time of ODCOD development. The datasets were aggregated and

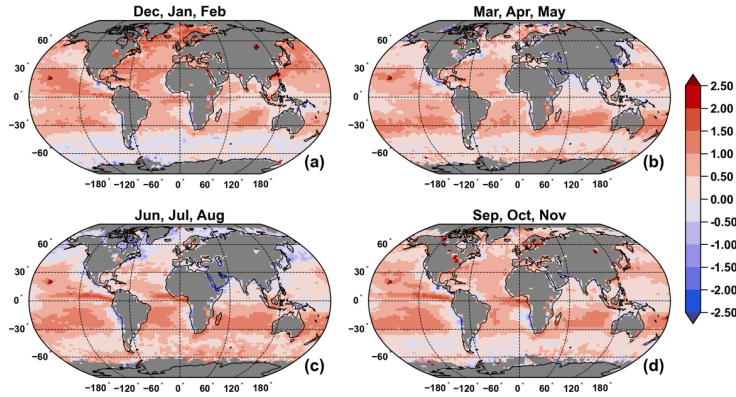

Figure 5: MERRA-2 wind speed corrections applied to wind speeds between 3–15 m s⁻¹ used in ODCOD 5 km aerosol-only retrievals for each of the four seasons, March 2008 through February 2011.

Figure 5 shows the median additive corrections applied to the MERRA-2 wind speeds between 3–15 m s⁻¹ used in ODCOD 5 km aerosol-only retrievals and illustrates that in nearly all regions an addition is required to correct the low bias in MERRA-2 winds. The latitude, longitude, season, and MERRA-2 wind speed of the CALIOP profile is used to calculate the bias correction by four-dimensional linear interpolation. In this way, a correction can be derived for any observation along the CALIPSO orbit track.

To estimate the uncertainty in the derived correction, analysis of the means and standard deviations in the AMSRE and AMSR2 data find the mean relative standard deviation for the correction factors as $\epsilon_{\omega_A} = 0.2537$. Since the correction factor is an additive bias correction, the overall relative uncertainty in the wind speeds used for ODCOD is estimated by Eq. (18).

$$\epsilon_{\omega} = \sqrt{\epsilon_{\omega_M}^2 + \epsilon_{\omega_A}^2} = \sqrt{(0.151)^2 + (0.2537)^2} = 0.2950 \quad (18)$$

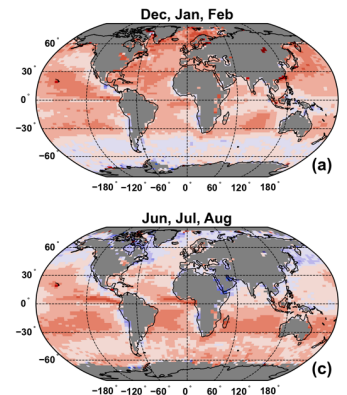

This means the variance is $\sigma_{\omega}^2 = \epsilon_{\omega}^2 \cdot (\omega_M + C_A)^2$ where C_A is the AMSR derived wind speed bias correction. Since wind speed is used to estimate both wave slope variance and whitecap fraction, wind speed plays a significant role in the uncertainty estimate.

¶ Within the ODCOD algorithm,

Wind speed is also used as a filtering criterion. Within the ODCOD algorithm, surface returns where wind speeds fall outside of the inclusive range (0.025–43) m s⁻¹ are not attempted. Estimating the reflectivity and fraction of whitecaps with Eqs. (3) and (4) introduces more uncertainty into the model but no analysis has been done at this time to determine the magnitude of that uncertainty. More discussion on filtering ODCOD data is found in Sect. 3.1.1.

2.2.2 Surface Return Area

Another source of uncertainty in the ODCOD algorithm comes from fitting the measured values of the surface return signal to the DIRM. This uncertainty arises from the measurements, which include both random noise and systematic biases such as calibration uncertainty and potential subsurface contributions to the signals, and from possible errors in the JRM representation of the true IRF output. The variance in the area is estimated from the squared differences between the measured surface return and the time shifted and scaled DIRM. We assume that all mentioned sources of uncertainty are captured by this fit error. Since the area is the integral of the JRM multiplied by the scale factor determined by the retrieval, the variance of the area is given by Eq. (19).

2.2.3 Additional Screening Inputs

Other inputs to the algorithm include the depolarization ratio of the surface return, the negative signal anomaly flag, and the surface saturation flags found in the CALIOP data products. ODCOD requires the surface depolarization ratio to be below 0.15 for a retrieval to be attempted. This threshold is an attempt to ensure that any surface returns with significant sea ice or surface debris are not attempted (Lu et al., 2017). This threshold may also filter out some shallow water cases where significant ocean bottom return could contaminate the retrieval, however a more stringent requirement may be desired if using coastal or shallow water data. Surface depolarization ratios are reported for all surfaces detected in the CALIOP V4.51 LL2 data products.

Deleted: meant

Deleted: retrievals from the ocean

Other considerations are the negative signal anomaly (NSA) and surface saturation. The NSA occurs when an unusually large negative attenuated backscatter coefficient is measured in a range bin immediately preceding a very large positive backscatter return from a strongly scattering target such as Earth's surface (Tackett et al., 2018). Since NSA cannot be determined whether they properly belong to the surface return or to the atmospheric return immediately above, these events

Deleted: signal

Deleted: it

Deleted: NSA

Deleted: ODCOD retrievals are not attempted when

690 are excluded from ODCOD processing. Also excluded are any profiles where surface saturation is detected. Surface saturation occurs when the magnitude of the signal received by the lidar detectors exceeds the maximum value the detectors can accurately measure. Surface saturation would lead to an improper fit of the JRM, and underestimate of A_{IRM} , and a high bias in the estimate of the column optical depth. Saturated surfaces are identified when the surface saturation flags reported in the LL1 product indicate surface saturation or possibly saturated data.

1695 2.3 ODCOD Output Products

CALIPSO V4.51 LL2 data products report 532 nm ODCOD effective optical depth estimates and uncertainties at 333 m, 1 km, and 5 km resolution as well as the MERRA-2 10 m wind speed components, the wind speed correction values, and an ODCOD QC flag. To calculate the wind speed used by ODCOD from these data products, a user must calculate the wind speed magnitude from the components and add the reported correction value.

- Deleted: full column

1700 The ODCOD QC flag is a 32-bit unsigned integer where each bit used has a specific meaning, as described in Appendix A. The flag is designed such that when interpreted as an integer value, any QC flag value below 64 is an attempted retrieval and the data could conceivably be used although further quality filtering as described in Sect. 3.1.1 should be considered.

3 Performance Assessment

705 In this section we assess ODCOD retrievals by comparing ODCOD aerosol optical depths (AOD) to collocated AOD retrievals from airborne High Spectral Resolution Lidar (HSRL) measurements and seasonally averaged AOD from two independent satellite-based retrieval techniques. To facilitate comparisons that are meaningful for scientific interpretation, data quality filtering is applied to each of the data sets to exclude suspected poor quality and anomalous data. The data selection procedure is described first for all data sets in Sect. 3.1, followed by the comparison analysis in Sect. 3.2.

1710 3.1 Data Selection

3.1.1 ODCOD Data Selection

Unless otherwise stated, all ODCOD data in the comparisons in Section 3.2 is from March 2008 through February 2011 and are the latest version 4.51 Lidar Level 1 (LL1) and V4.51 LL2 data products. We select data for aerosol-only profiles, where CALIOP has not detected clouds at any resolution, within a given retrieval column. This is important because ODCOD is always a total column optical depth estimate with no way to isolate different feature types in the vertical profile. To select the highest quality ODCOD retrievals, the limitations of the ODCOD models and the CALIOP instrument are considered to guide filtering criteria. Unless otherwise stated, the following data quality filters are applied to all data in the comparisons in

this paper. Selecting retrievals with wind speeds in the range 3–15 m s⁻¹, surface integrated attenuated backscatter at 532 nm (SIAB) < 0.0413 sr⁻¹ in the daytime or < 0.0353 sr⁻¹ in the nighttime, and surface integrated depolarization ratio 532 nm (SIDR) < 0.05 improves agreement of ODCOD to the other datasets presented and should be considered when using the ODCOD product.

Filtering profiles where the wind speeds fall outside the range 3–15 m s⁻¹ will retain approximately 94 % of retrievals and provide ocean reflectivity estimates for which the model is mostly in the less complex ocean water regime with only a small fraction of the total reflectivity attributed to white caps. To use nearly exclusively ocean water reflectance, a stricter requirement of 3–8 m s⁻¹ could be used, but this restriction only retains on the order of 51 % of retrievals and does not significantly improve how the data compares to other optical depth estimates over the 3–15 m s⁻¹ filter.

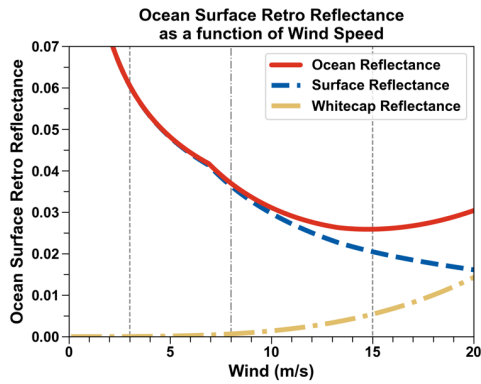

Figure 6: The ODCOD ocean surface retro reflectance model at 532 nm and off nadir angle of 3° as a function of wind speed with markers at 3 m/s, 8 m/s, and 15 m/s as reference for possible filter thresholds.

The ODCOD ocean surface reflectance model, described by Eq. (3) and shown in Fig. 6, approaches an asymptotic value as the wind speed approaches 0 m s⁻¹ and as a result increases rapidly when the wind speed drops below 3 m s⁻¹. The large change with small variations of wind speed makes the estimate of surface reflectivity in this part of the model significantly less certain. Filtering profiles with wind speeds less than 3 m s⁻¹ removes on the order of 7 % to 8 % of profiles and avoids surface reflectivity estimates in the region of the model with higher variability. Furthermore, as wind speeds increase much above 8 m s⁻¹, the contribution of whitecaps to ocean reflectance increases. Because instantaneous white cap reflectivity is known to be a complex amalgam of multiple factors in addition to wind speed (Dierssen, 2019), ODCOD's wind speed-only white cap reflectivity estimate becomes increasingly less certain at higher wind speeds. Filtering profiles with wind speeds

greater than 15 m s^{-1} removes on the order of 1 % to 2 % of retrievals and avoids surface reflectivity estimates with significant contribution from whitecaps.

ODCOD does not attempt a retrieval when the CALIOP surface saturation flags show surface saturation or possibly saturated data. However, because samples are averaged vertically prior to downlink, surface saturation can still go undetected. In this study, we filter profiles with $\text{SIAB} > 0.0413 \text{ sr}^{-1}$ in the daytime and $> 0.0353 \text{ sr}^{-1}$ in the nighttime which removes approximately 20 % of ODCOD profiles day or night but captures approximately 98 % of profiles where SIAB corresponds to surface saturation (Fig. 7). The upper panels of Fig. 7 show distributions of SIAB versus windspeed for aerosol-only profiles having valid ODCOD retrievals. The lower panels show SIAB versus windspeed for surface-saturated aerosol-only profiles for which no ODCOD retrieval was attempted. The horizontal red lines seen in all four panels represent the SIAB threshold above which valid ODCOD retrievals are considered suspicious due to possible undetected surface saturation.

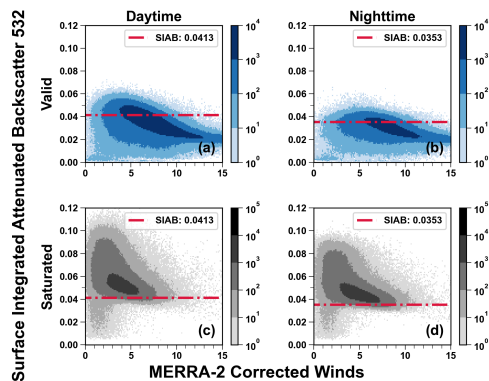

Figure 7: The top row shows SIAB at 532 nm as a function of wind speed for CALIOP determined aerosol-only 5 km ODCOD valid retrievals for daytime (left) and nighttime (right) measurements; distributions on the bottom row show SIAB as a function of wind speed for surface-saturated aerosol-only 5 km profiles for which ODCOD retrievals are not attempted. The red dashed line shows the proposed thresholds for day and night.

The magnitude of surface return signal that will saturate the detectors is different in the day and night due to the difference in CALIOP variable gain amplifier settings (Hostetler et al., 2005). High, and highly variable, solar background signals during daytime operations dictate the use of lower amplifier gains to minimize digitizer overflows in the daytime measurements.

Daytime gains are lower by a factor of approximately 6.5, which accounts for the difference in the day and night SIAB thresholds and explains why different distributions can be seen day and night (Fig. 7(a) and Fig. 7(c), and Fig. 7(b) and Fig.

7(d), respectively). On the order of 27 % of daytime aerosol-only profiles over ocean are rejected for ODCOD retrieval due

1890 to flagged surface saturation and that number increases to 43 % at night. Using the median and MAD of the SIAB
 distribution of saturated profiles shown in Fig. 7(c) and Fig. 7(d), we calculate the thresholds for the SIAB filter, from the
 median of the SIAB (0.0543 daytime and 0.0457 nighttime) minus two times the MAD.

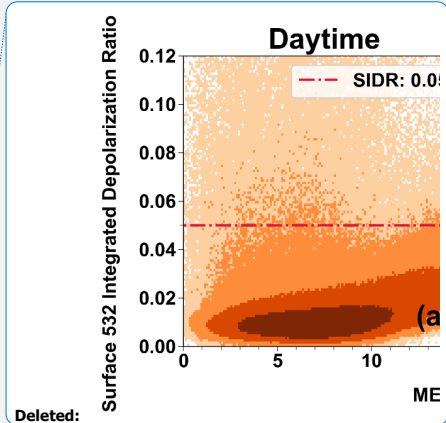

Deleted: are calculated

895 In this study, we also filter profiles with SIDR greater than 0.05. This threshold removes 1 % to 2 % of the ODCOD profiles.

Deleted: ODCOD retrievals are not attempted

ODCOD does not attempt a retrieval when the SIDR is greater than 0.15 to avoid retrievals over ocean covered by ice.
 However, small amounts of sea ice, surface debris, and ocean bottom returns in shallow water are all places where the SIDR
 might be elevated and the ODCOD retrieval would be attempted but may be invalid. Figure 8 shows the distribution of SIDR
 for CALIOP determined aerosol-only profiles for valid ODCOD retrievals as a function of wind speed.

Deleted: lower confidence. In this study, profiles with SIDR greater than 0.05 are also filtered out. This threshold removes 1 % to 2 % of the ODCOD profiles.

Deleted:

1900 Figure 8: SIDR as a function of wind speed for CALIOP determined aerosol-only 5 km ODCOD valid retrievals in daytime (left) and nighttime (right) with the SIDR filtering threshold of 0.05 marked with a dashed red line.

Figure 8 shows a tight distribution of SIDR values around the median of approximately 0.01 for valid aerosol-only ODCOD retrievals. While there appears to be a slight wind speed dependence, we use this simple threshold to filter profiles with SIDR greater than 0.05 to remove the larger outliers from the distribution.

Deleted: The 0.05 SIDR threshold is used

1905 3.1.1.2 Airborne HSRL Data Selection

To assess how well ODCOD performs against airborne HSRL measurements, we compare ODCOD 5 km retrievals to AODs measured by Langley Research Center's High Spectral Resolution Lidar (HSRL-1) (Hair et al., 2008) and High Spectral Resolution Lidar Version 2 (HSRL-2) (Burton et al., 2018; Ferrare et al., 2023). The HSRL instruments provide quality atmospheric measurements from high altitude aircraft. HSRL-1 and its successor HSRL-2 have been operating in various field campaigns since 2006. We compare ODCOD 5 km retrievals to measurements acquired by the HSRL-1 and HSRL-2

during campaigns in which CALIPSO overpasses occurred. The dates and HSRL field campaigns during which these CALIPSO underflights occurred can be found in Appendix B.

925 These scenes were selected from 152 CALIPSO underflights conducted by the Langley HSRL team. The selection process was performed by considering the time and distance of each measurement to the coincident CALIPSO overpass 5 km footprint. The selection criteria require the HSRL measurement and associated ODCOD 5 km retrieval midpoint to have a time difference of less than 60 minutes and a spatial offset of less than 5 km. We choose to use 5 km ODCOD profiles because ODCOD averages the surface returns before retrieving and provides a more consistent retrieval over the scene. We also apply the ODCOD filters described in Sect. 3.1.1 for aerosol-only profiles. Once collocated and filtered, we require a minimum of four matching ODCOD 5 km retrievals in the flight and require that no atmospheric features be reported in CALIOP's LL2 vertical feature mask above the HSRL data top altitude (approximately 8.5 km) of the matching points. Due to the locations of available underflights that satisfy these conditions, the scenes used occur exclusively in the North American and Venezuelan Basins of the Atlantic Ocean, as shown in Fig. 9.

935 Figure 9: Locations of the HSRL underflights used in the comparisons to ODCOD 5km.

The HSRL processing calculates AOD for a given profile directly from the measured molecular channel and estimated molecular backscatter coefficients of the atmosphere computed from reanalysis model temperature and pressure data, (Hair et al., 2008). Rogers et al. (2009) compared HSRL profiles of aerosol extinction and AOD results to established measurements and found agreement within 0.01 km^{-1} for extinction and 6% for AOD (532 nm). The HSRL aircrafts fly significantly lower than CALIPSO, so when comparing AODs it is critical to consider light extinction above the altitude at which the HSRL measurements begin. The CALIOP signal will attenuate between the CALIOP and HSRL data top altitudes and must be accounted for when comparing HSRL and ODCOD AOD retrievals to estimate similar quantities. Even if no

focus of the paper, CALIOP's standard cirrus retrievals have already been well-validated with airborne lidar (Hlavka et al., 2012) and MODIS (Holz et al., 2016) and can be confidently used for studying cirrus clouds. While ODCOD does provide an estimate when transparent water clouds are present, a significant effort remains to understand the multiple scattering effects of water clouds on ODCOD and the significant impact on the reported optical depths.

Figures 10 and 11 show seasonal aerosol-only ODCOD optical depths in 5 km profiles filtered as described in Sect. 3.1.1, where no clouds are detected by CALIOP. Elevated values are seen in regions where high aerosol loading is expected: Saharan dust outflow is evident in the tropical Atlantic Ocean in June–August (e.g., Ridley et al., 2012), Asian dust is evident over the northern Pacific Ocean in March–May (e.g., Liu et al., 2013), and smoke from biomass burning is discernible off the southwest Africa coast in September–November (e.g., Yu et al., 2012) despite persistent marine stratocumulus in the region. These regional patterns of enhanced optical depth are consistent with AOD observed by MODIS (Remer et al., 2008).

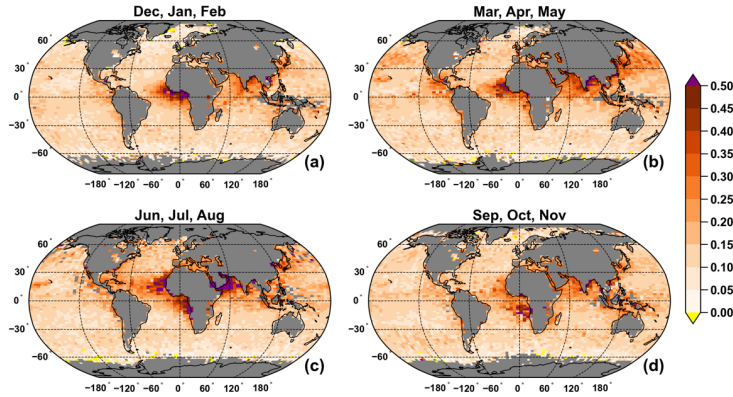

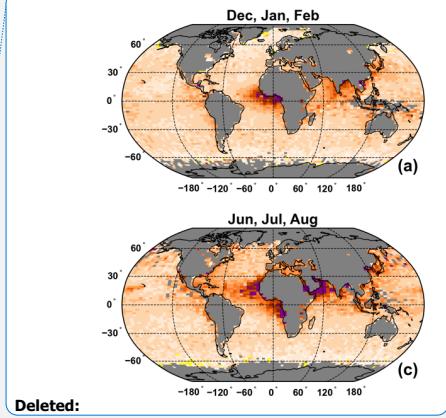

Figure 11: Nighttime seasonal median ODCOD aerosol optical depth, March 2008 through February 2011.

Globally, the average optical depth reported by ODCOD is higher at night compared to the day (Fig. 12). This is at least in part due to the sampling bias caused by the greater occurrence of surface saturation at night due to differences in CALIOP's daytime and nighttime detector gains (Hunt et al., 2009). Because ODCOD retrievals are not performed on profiles with saturated surface returns, which preferentially occur in low optical depth scenes, successful nighttime ODCOD retrievals yield higher average optical depths compared to those during the day. The average nighttime optical depth is higher because the lower optical depth columns are not represented; the median optical depth difference is on the order of 0.03 ± 0.07 higher at nighttime with a relative difference of around 22 % globally. Statistically, we can evaluate the differences between day and night using an unequal variance t-test which shows that the null hypothesis p-value $\ll 0.05$ and the 95 % confidence interval for night minus day is approximately 0.026 to 0.027. Regionally some differences are much greater.

Solar background noise introduces another source of day-night bias. In columns with high particulate optical depths, detection of the surface returns used by ODCOD requires distinguishing a strongly attenuated surface peak from the ambient background noise. In cloud-free skies over oceans, CALIOP's daytime SNR is, conservatively, a factor of around 6 lower than at night, resulting in a much broader daytime background noise envelope in the region of tenuous surface returns. This large noise enhancement impedes the detection of attenuated surface peaks, and thus truncates the high end of the daytime ODCOD distribution at a substantially lower value than at night. However, the fraction of ODCOD aerosol-only profiles that have an optical depth greater than 1.0 at both day and night is less than 0.1 % and thus have little effect on the statistics here and are not considered.

While some of [this](#) day-night AOD difference could be due to true natural variation in daytime [and](#) nighttime [aerosols](#) or an unaccounted-for bias in the wind speed data day to night, a [significant](#) portion is due to this saturated surface sampling bias which is especially acute when averaging cloud-free columns. The absence of solar background noise during nighttime observations allows optically thin clouds to be detected much more often at night, [which in turn](#) will also cause a sampling bias when attempting to study aerosol-only profiles because fewer profiles in general will be considered aerosol-only at night and more clouds will go undetected in the daytime (Liu et al., 2019).

The data for Fig. 12 has been filtered as described in Sect. 3.1.1 with separate SIAB thresholds used for day and night.

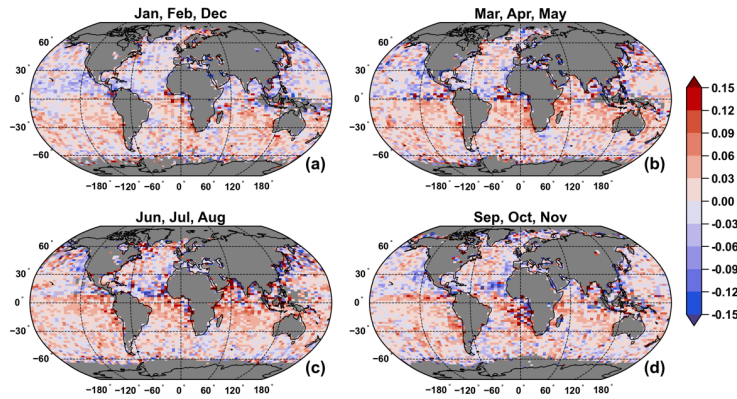

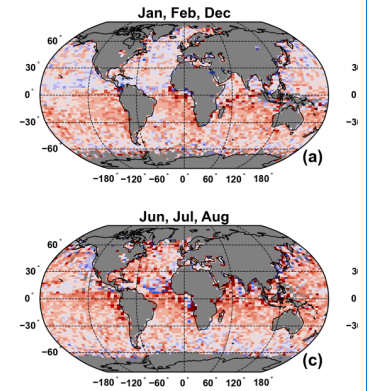

Figure 13: Nighttime median minus daytime median seasonal ODCOD aerosol optical depth differences with daytime SIAB filter applied to both day and night, March 2008 through February 2011.

To demonstrate the impact of the surface-saturation sampling bias, we experimentally modified the surface saturation filter described in Sect. 3.1.1 to use the nighttime SIAB threshold for both day and night observations. It is critical to understand that by applying the same SIAB threshold filter, we are removing some good-quality low daytime data that will no longer be represented in the average. The median night minus day differences in Fig. 13 shows that the daytime median optical depth drops to 0.010 ± 0.006 , or about 7% relative difference. Statistically, we still find a slight difference between night and day, with the unequal variance t-test which showing that the null hypothesis p-value $\ll 0.05$ but the 95 % confidence interval for drops to approximately 0.004 to 0.005. This experiment confirms that the sampling bias from surface-saturation differences day and night is a significant contributor to the day to night differences in ODCOD retrievals.

3.2.2 ODCOD at Different Spatial Averaging Resolutions

ODCOD is reported in the CALIOP LL2 data products at single shot (333 m), 1 km, and 5 km resolutions. For the 1 km and 5 km data products, the ODCOD algorithm uses the averaged surface return detected at each resolution rather than averaging finer resolution ODCOD retrievals. By averaging the surface return before retrieval, the ODCOD Impulse Response Model (IRM) fitting procedure has a better chance of correctly fitting the IRM to the surface points. Even a relatively small noise perturbation to one of the two surface return points used to fit the IRM can cause the time delay to be incorrectly estimated which typically results in a surface return area that is too small and thus an optical depth that is too large.

This average-then-retrieve approach is important because averaging finer resolution retrievals would bias the coarser resolution low anytime the surface was not detected in all finer resolution profiles. For example, if a retrieve-then-average

approach were used to estimate ODCOD at 5km and only some of the 15 single shots within the 5km average detected the ocean surface, only those that did detect the surface would have valid ODCOD retrievals to average. Only averaging the surface-detected ODCOD retrievals would mean not accounting for the very high optical depths of the missing retrievals, and the estimate would be bias significantly low. More missing single shot estimates also means a more significant bias. By averaging the surface return backscatter data for all 15 shots regardless of if they detected a surface or not, ODCOD is better representing the ocean return magnitude for the 5km profile and the optical depth CALIOP is able to detect. However, we must recognize that an estimate of the optical depth with totally attenuated single shot columns within averaged profiles will still not represent the overall optical depth of the 5km column as the lidar does not fully penetrate the atmosphere to the ocean surface in those regions.

Deleted: schemes can offer an alternative to the average-then-retrieve approach.

Deleted: care

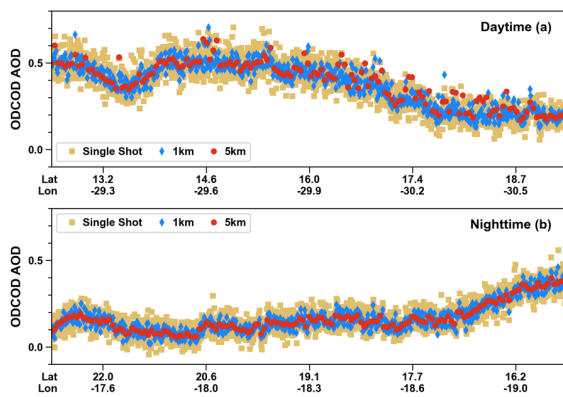

Figure 14: ODCOD retrievals of aerosol-only profiles as determined by CALIOP at single shot (333 m) (yellow squares), 1 km (blue diamonds), and 5 km (red circles) resolutions for a daytime and nighttime scene in panels (a) and (b) respectively. The daytime scene is over the international atomic times 2008-05-05T15:33:30 to 2008-05-05T15:35:24 and the nighttime scene is 2008-05-28T03:08:19 to 2008-05-28T03:10:18.

Figure 14 shows a daytime and nighttime scene selected for having a large number of consecutive aerosol-only ODCOD retrievals with filtering according to Sect 3.1.1. In general, the retrievals show that the 5 km retrievals are less noisy and fall on top of the 1 km retrievals, which are again less noisy and fall on top of the single shot retrievals. In the daytime, the effects of the solar background radiation can be seen from the larger spread of the data at each resolution as well as occasional deviations of the resolutions from lying directly on top of one another. However, nighttime is very well behaved and shows how well the ODCOD average and retrieve technique does when not having to contend with solar background noise.

Typically using the coarsest resolution ODCOD data is the right choice for analysis however, with proper selection and taking care to not bias averages, averaging finer resolution retrievals can also provide reasonable estimates.

3.2.3 Comparisons to airborne HSRL

In general, ODCOD 5 km compares well with HSRL aerosol optical depth retrievals and shows little to no bias when day and night are considered together, with the median difference being 0.009 ± 0.043 ($6\% \pm 28\%$ relative difference; $N=395$) with ODCOD higher. A paired sample t-test shows the difference is not statistically significant with a p-value of 0.36 and a 95 % confidence interval for the mean difference of -0.005 – 0.014 . Separately, ODCOD compares slightly lower in the daytime and slightly higher at night but with uncertainties larger than the difference in either. The median difference in the daytime is -0.037 ± 0.052 ($-12\% \pm 25\%$; $N=149$) with ODCOD lower, the p-value shows the difference is statistically significant, and the 95 % confidence interval for the mean difference is -0.044 to -0.019 . The median difference at night is 0.021 ± 0.032 ($14\% \pm 25\%$; $N=246$) with ODCOD higher, the p-value also shows the difference is statistically significant, and the 95 % confidence interval for the mean difference is 0.014 to 0.039 .

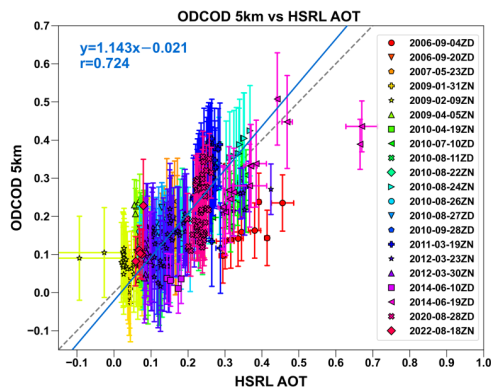

Figure 15: HSRL AOD compared to 5 km ODCOD retrievals for 21 select HSRL underflights of CALIPSO. The dashed grey line is the one-to-one line and the solid blue line is the orthogonal best fit line with fit parameters shown in blue in the upper left corner.

Figure 15 shows the collocated and quality filtered 5 km ODCOD retrievals as a function of above-aircraft adjusted HSRL measurements from the 21 CALIPSO underflights that met the selection criteria outlined in Sect. 3.1.2. The HSRL values are mean values computed over the ODCOD 5 km averaging interval, with the standard deviation of the HSRL measurements shown as the error bars. The error bars of the ODCOD retrievals show the reported ODCOD standard deviation estimates from the LL2 data products. Spatial and temporal collocation differences will introduce some uncertainties into these one-to-

2625 3.2.4 Comparisons to MODIS

In general, the global median difference between ODCOD 5 km daytime retrievals and MODIS interpolated 532 nm AOD is -0.009 ± 0.041 ($8\% \pm 35\%$; $N=1,999,068$) with ODCOD lower. Applying a paired sample t-test shows the differences are statistically significant but the 95 % confidence interval for the mean difference is -0.0069 to -0.0067 . Regionally, ODCOD tends to report higher aerosol optical depths in the southern oceans from March through August and seems to swing to lower optical depths in December through February. ODCOD also tends to report higher aerosol optical depths north of 30° N from September through February but the difference is less during March through August.

Table 2: Statistics summarizing the comparison results. Each row summarizes the seasonal sets of months designated by the first letter of the months in question such as December, January, and February as DJF with the final row labelled Yearly as the total statistics for all data March 2008 through February 2011.

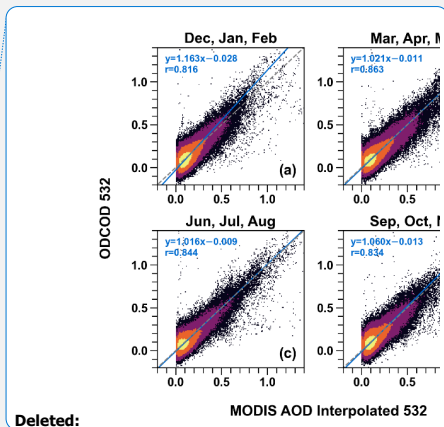

Figure 16: Collocated ODCOD aerosol optical depth at 5 km resolution on the y-axis and MODIS effective optical depth average ocean collocated and interpolated in latitude, longitude, and wavelength the midpoint of the CALIOP 5 km profile and 532nm wavelength, March 2008 through February 2011.

Unlike ODCOD, which permits negative optical depths, the MODIS algorithm reports an optical depth of zero when the observed top of the atmosphere is greater than or equivalent to the Rayleigh plus surface signal. While negative optical depths are non-physical, they arise due to random noise in the original measurements and thus should be retained when computing statistics to avoid introducing high biases when estimating means, medians, correlations, and lines of best fit. Removing data pairs where MODIS reports zero only slightly improves correlation with differences of only a few thousandths and slightly increases the slope with differences of only a few hundredths and does not significantly change the resulting statistics. Globally, the median difference with zeros excluded is still statistically significant at -0.010 ± 0.041 (8% \pm 35% relative difference; $N=1,979,372$) again with ODCOD slightly lower and the 95% confidence interval for the mean difference still -0.0069 to -0.0067 . Simply removing data pairs where MODIS reports zero may bias the comparison in other ways and since the zeros removed comparison shows little to no significant difference, we consider the comparisons presented reasonable.

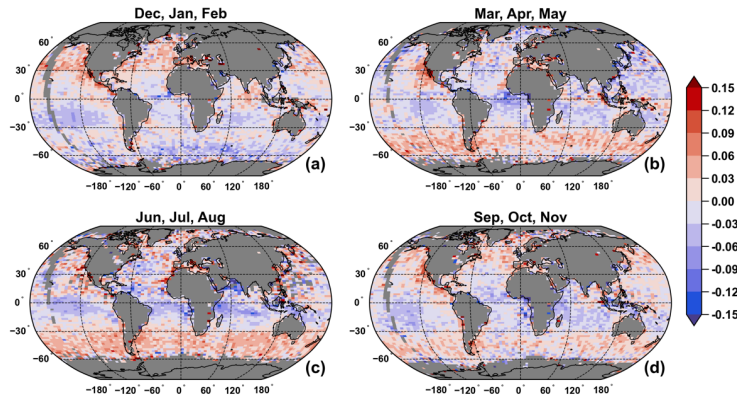

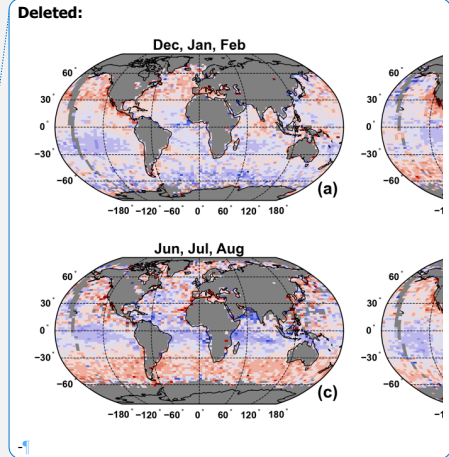

Figure 17: ODCOD minus MODIS aerosol optical depth difference of the median values, ODCOD higher shown in red and ODCOD lower shown in blue, March 2008 through February 2011.

The maps in Fig. 17 provide seasonal depictions of the regional differences between daytime AOD retrieved by MODIS and 5 km ODCOD. The data shown in these maps are the same data shown in Fig. 16 with the difference of the medians of each bin presented regionally. Figure 16(b) and Fig. 16(c) show notable differences, with ODCOD higher on the order of 0.03 to 0.06 in the Southern Ocean from March through August. These differences largely disappear from September through February. It is also important to consider data filtering in these results. While cloudy pixels are screened by the MODIS algorithm and ODCOD has been screened for clouds along the 5 km track, regions where thin cirrus clouds are frequently found have a higher chance of undetected clouds in the ODCOD retrieval and cloud contamination in the MODIS retrieval. Cloud contamination could be a source of bias in this comparison as it is known that cloud contamination can bias MODIS high (Spencer et al., 2019; Reid et al., 2022). Also, regions where clouds are detected more frequently will be sampled less often. Additionally, the larger 10 km MODIS pixel compared to the ODCOD 5 km swath will introduce artifacts into the comparison due to the difference in sampling.

3.2.5 Comparisons to SODA

In general, ODCOD 333 m retrievals compare well with SODA 333 m daytime aerosol optical depth retrievals and show a relatively small difference globally. The daytime median difference is 0.004 ± 0.035 (1% \pm 34% relative difference; N=21,270,202), ODCOD higher. Applying a paired sample t-test shows the differences are statistically significant but the 95% confidence interval for the mean difference is 0.0044 to 0.0045. In the nighttime, ODCOD 333 m reports higher values than SODA, with a nighttime median difference of 0.027 ± 0.034 (20% \pm 33% relative difference; N=10,536,357), ODCOD higher. The paired sample t-test shows the differences are statistically significant with the 95% confidence interval for the

Deleted: the

Deleted: is

Deleted: a correlation coefficient of 0.879. Unexpectedly, SODA reports

Formatted: Font: +Body (Times New Roman)

mean difference being about 0.028. SODA has statistically similar values both day and night with median values of 0.102 ± 0.045 daytime and 0.105 ± 0.045 nighttime. Statistically higher optical depths at night due to better surface detection is expected in both datasets as SODA and ODCOD are filtered one-to-one, ODCOD requires a valid surface detection, both are the same footprint, and both use CALIOP data as an input. We would expect the nighttime retrievals to be on the order of 0.02 higher at night as demonstrated in Sect. 3.1.1. Even though the CALIOP data used by SODA version 2.3 and 2.31 is CALIOP LL1 version 4.1, the surface saturation does not change between versions although, calibration changes were made to the CALIOP V4.51 data products polarization gain ratio which improved the CALIOP calibration between version 4.1 and V4.51 (Getzewich et al., 2024). Other than the described nighttime differences, we find the comparisons between ODCOD and SODA to be good and generally acceptable.

During analysis, it was found that SODA has occasional anomalous data that is not filtered by the SODA scene or quality assurance flags. This artifact becomes apparent when plotting ODCOD as a function of SODA, as the anomalous points form striated lines in what appear to be somewhat quantized groupings, many of which are relatively large negative values. The anomalous points can be clearly seen in Fig. 18 and Fig. 19. Preliminary investigations indicate that one primary cause of these SODA outliers is the inadvertent use by the SODA algorithm of CPR data acquired during CPR calibration maneuvers (Tanelli et al., 2008).

To separate the anomalous data from quality data, the SODA data is binned by the matching ODCOD data in 0.01 optical depth bins and Tukey fences are calculated for each bin. Carling (2000) defines “Tukey’s rule” for identifying outliers in a data set as $c_{low} = q_1 - k_1(q_3 - q_1)$ and $c_{high} = q_3 + k_1(q_3 + q_1)$, where, “ q_1 and q_3 are the sample quartiles [...] and k_1 is a constant selected to meet a pre-specified outside rate under some model” and c_{low} and c_{high} are, respectively, the cut-off points beyond which points in the lower and upper tails of the distribution are deemed to be outliers. In our case the pre-specified constant is set to $k_1 = 4.5$ based on visual inspection of the joint distribution (e.g., Figs. 18 and 19). This value retains approximately 99.8 % to 99.9 % of data and clearly labels the anomalous distributions.

Table 3 and Figs. 18 and 19 show how ODCOD at single shot resolution compares to SODA CPR during the day and night for all CALIOP data acquired from March 2008 through February 2011 that fall within the described outlier envelope.

	Mean \pm Std. Dev.		Median \pm M.A.D.		Mean of Differences (ODCOD - SODA CPR)	Median of Differences (ODCOD - SODA CPR)	Number of Samples

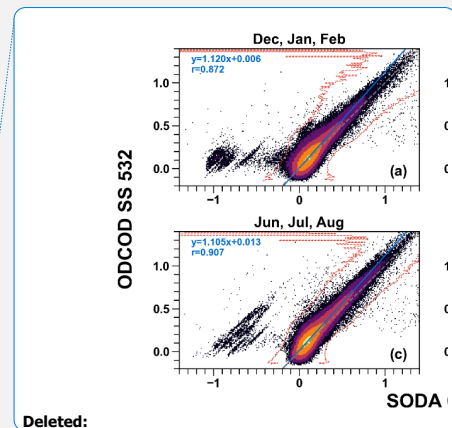

Figure 19: Depicts the same information as Fig. 18, but for nighttime observations.

Due to the CloudSat battery anomaly that occurred in April of 2011, CloudSat nighttime data and subsequently SODA CPR retrievals at night are not available after that time. The ODCOD algorithm itself makes no distinction between day and night and [we are not currently aware of significant](#) differences in the inputs to the algorithm at day versus night. CALIOP's version 4.1 calibration has been extensively validated during both nighttime and daytime operations (Kar et al., 2018; Getzewich et al., 2018) [and the changes to the V4.51 calibration has shown improvements over version 4.1 \(Getzewich et al., 2024\)](#). [We note](#) that SODA incorporates its own calibration adjustments to the input data [and applies a second nighttime only calibration](#) (Josset et al., 2010). [The reason](#) for the differences [at night compared to](#) SODA CPR are not well enough understood to comment further.

3.2.6 Results Summary

The results of all comparisons performed are summarized in Table 4, which shows that even among established datasets the agreement can vary, but ODCOD agrees well on most accounts, especially in the daytime. At nighttime, ODCOD tends to trend slightly higher than the datasets examined, but the lack of well validated [and confident](#) nighttime data makes comparisons to ODCOD [in the nighttime](#) more difficult.

4 Future Work with CALIOP

Comparing ODCOD optical depth retrievals to the CALIOP standard retrievals present unique opportunities for analysis and improvement to the CALIOP standard algorithms. Since the only CALIOP LL2 algorithm ODCOD relies on is the surface detection algorithm (Vaughan et al., 2017) and the surface detection algorithm only requires the LL1 attenuated backscatter signal about the surface, ODCOD's optical depth estimates are independent from CALIOP's standard V4.51 LL2 reported optical depths.

One of CALIOP's primary goals is to retrieve vertically resolved profiles of particulate extinction coefficients which can then be integrated to calculate an estimated column optical depth. To retrieve extinction coefficients, CALIOP uses a feature detection algorithm to first isolate regions of the vertical profile with elevated attenuated backscatter (Vaughan et al., 2009), then prescribes an extinction-to-backscatter ratio (i.e., lidar ratio) for various aerosol types based on the CALIOP aerosol classification (Omar et al., 2009) and cloud/aerosol discrimination algorithms (Liu et al., 2019; Avery et al., 2020; Kim et al., 2018; Young et al., 2018). However, CALIOP only reports extinction coefficients for regions of the vertical profile where the attenuated backscatter signal is above the detection threshold (McGill et al., 2007). Regions of faint scattering from diffuse particulates will fall below these limits and hence go undetected. This inherently means that a small fraction of the overall particulate extinction will not be included in CALIOP's column optical depth estimates. Kim et al. (2017) estimate CALIOP's undetected optical depth to be on the order of 0.030 ± 0.046 . Based on comparisons to MODIS, Toth et al. (2018) report similar estimates of 0.03 to 0.05 for daytime retrievals. Consequently, estimates of global mean aerosol

Moved (insertion) [2]

Moved up [16]: CALIOP's standard cirrus retrievals have already been well-validated with airborne lidar (Hlavka et al.,

Deleted: Compared to 10 airborne HSRL collocated under flights, ODCOD 5 km retrievals show a correlation of 0.775 computed over 149 samples. Compared to 3 years of collocated daytime MODIS AODs interpolated to 532 nm, ODCOD 5 km retrievals show a correlation of 0.834 computed over 1,999,068 samples. One-to-one comparisons of daytime ODCOD and SODA 333 m retrievals show a correlation coefficient of 0.887 computed over 21,270,392 samples. For nighttime comparisons, the correlation coefficient for 11 airborne HSRL underflights compared to ODCOD 5 km retrievals is 0.721 computed over 246 samples. For 3 years of 333 m SODA retrievals compare to 333 m ODCOD retrievals, the correlation coefficient is 0.891 computed over 10,550,975 samples. ¶

Because retrievals are attempted whenever CALIOP detects the ocean surface, ODCOD has the potential to be used for studying cirrus and water clouds as well as aerosols. However, clouds are not the focus of the performance assessment in this paper. For studies of cirrus clouds,

2840 direct radiative effect derived from CALIOP's standard AOD retrievals are biased low by ~54 % (Thorsen et al., 2017). One of the drivers of developing the ODCOD algorithm was to provide an internally consistent assessment of fraction of the column optical depth that lies below CALIOP's direct detection thresholds. A comprehensive assessment of the CALIOP standard algorithms based on ODCOD retrievals lies well outside the scope of this paper. However, we provide some general observations to demonstrate the types of questions that an ODCOD versus CALIOP standard analysis could potentially answer.

2845 We compare ODCOD 5 km retrievals to column optical depths calculated from the CALIOP standard stratospheric and tropospheric range resolved extinction coefficient retrievals reported in the CALIOP LL2 profile products. Comparisons with CALIOP standard products are done where CALIOP extinction QC flags report 0 (unconstrained retrieval), 1 (constrained retrieval), or 2 (initial lidar ratio reduced) to ensure a quality extinction profile, as well as the ODCOD filters described in Sect. 3.1.1 for aerosol-only profiles. While all profiles were screened to ensure no clouds were detected in the 5 km profile, no attempt was made to further filter the CALIOP data based on overlying clouds in adjacent profiles which might increase errors in the extinction retrievals of any 20 km or 80 km horizontally averaged layer extinction or cloud aerosol discrimination. All data is compared one-to-one such that both datasets require a valid retrieval to be used in this analysis.

2850 In general, the ODCOD 5 km retrievals are expectedly higher than the CALIOP standard algorithm for retrieving aerosol optical depths. As suggested by Kim et al. (2017) the expected bias should be on the order of 0.030 ± 0.046 . Figures 20 and 21 compare CALIOP standard aerosol-only optical depths to 5 km ODCOD retrievals in the same profiles for day and night respectively. The daytime median difference is 0.025 ± 0.047 (34 % \pm 67 % relative difference; N=2,209,551) with ODCOD higher. Applying a paired sample t-test shows the differences are statistically significant and the 95 % confidence interval for the mean difference is near 0.024. The nighttime median difference is 0.046 ± 0.047 (60 % \pm 71 % relative difference; N=1,037,873) again, with ODCOD higher. The t-test shows these differences are also statistically significant and the 95 % confidence interval for the mean difference is near 0.041.

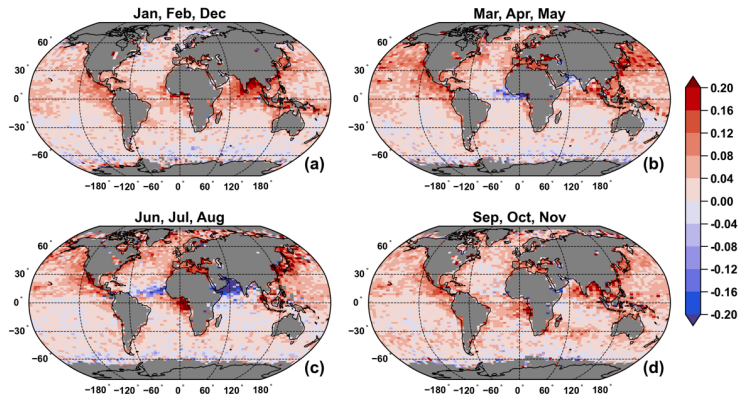

2865 [Figure 20: Daytime ODCOD aerosol optical depth at 5 km resolution as a function of CALIOP column optical depth for March 2008 through February 2011.](#)

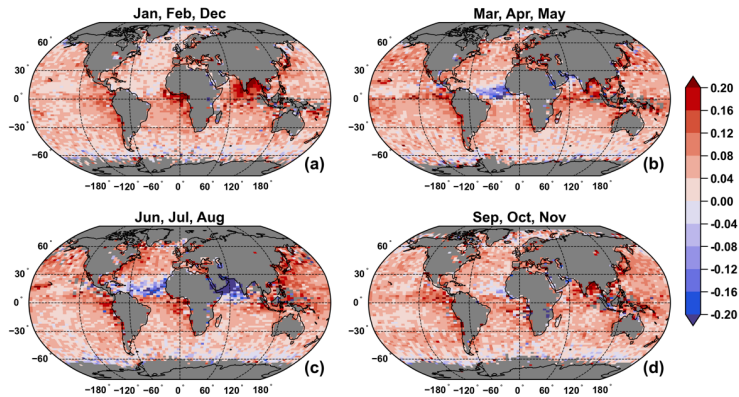

2870 [Figure 21: Nighttime ODCOD aerosol optical depth at 5 km resolution as a function of CALIOP column optical depth for March 2008 through February 2011.](#)

[This nighttime difference is larger than the day but attempting to estimate the global difference is difficult which is made apparent in Figs. 22 and 23. Some regions show strong positive and negative differences that vary significantly with season. Also, CALIOP's ability to detect clouds and aerosols is different at day than it is at night which will change the distribution of samples considered as aerosol-only profiles.](#)

2875 **Figure 22: Daytime aerosol optical depth difference (ODCOD - CALIOP) of the median values, ODCOD higher shown in red and ODCOD lower shown in blue for March 2008 through February 2011.**

2880 **Figure 23: Nighttime aerosol optical depth difference (ODCOD - CALIOP) of the median values, ODCOD higher shown in red and ODCOD lower shown in blue for March 2008 through February 2011.**

Figures 22 and 23 show how 5 km ODCOD compares to CALIOP 5 km column optical depths in the day and night, respectively. The most obvious difference is that, in general, larger values are retrieved by ODCOD in the northern hemisphere in the daytime and more globally at night. We expect ODCOD to be higher in general because it includes

extinction contributions from aerosols that are not detected by CALIOP's feature detection algorithm. At the same time, we expect more undetected aerosols to be missed by CALIOP in the daytime due to noise from solar background radiation. More study is needed to understand what drives the larger differences observed at night.

Some regional differences include the apparent stronger outflow of aerosols from Asia into the northern Pacific in March through August according to ODCOD. This could occur for a variety of reasons. Aerosol layers that are geometrically thick, yet optically thin might be missed by CALIOP feature detection or the applied lidar ratio may be too low. The ODCOD retrieval might be too high due to a regional bias in the modelled wind speeds or due to unaccounted differences in ocean reflectivity from expected model values.

In the Arabian Sea and Bay of Bengal region, ODCOD optical depths are much smaller than those of the CALIOP standard retrieval in June – August. Mixtures of dust and marine aerosol are common in this region due to the outflow of dust from the Arabian Peninsula (Satheesh et al., 2006). The CALIPSO standard algorithm typically classifies these layers as 'dusty marine' and assigns a lidar ratio of 37 sr, which might be too high on average. Likewise, ODCOD optical depths are lower in the Saharan dust outflow region in the tropical Atlantic. This could be indicative of high-biased lidar ratios for pure dust or marine-dust mixtures in this region. However, we are not drawing conclusions here and a rigorous analysis is needed to evaluate these questions.

5. Conclusions

CALIPSO's Version 4.51 Lidar Level 2 data products report a new estimate of total column effective optical depth derived from the ocean surface lidar backscatter return by the Ocean Derived Column Optical Depths (ODCOD) algorithm. Multiyear comparisons show that ODCOD daytime estimates of aerosol optical depth (AOD) have statistically significant differences to several established and validated datasets, but those differences are generally small on the order of several thousandths. Relative to daytime retrievals, ODCOD nighttime AOD estimates tend to be higher; however, in-depth global comparisons are hindered by the lack of well understood and validated nighttime data derived from other sensors. Different CALIOP amplifier gains during the daytime and nighttime portion of the orbit cause the lidar surface return to saturation more frequently at night and the lack of solar background radiation also allows the surface to be detected more readily when the surface return is very small. Since ODCOD requires unsaturated surface detections, both effects will cause a statistical sampling bias of nighttime higher than daytime. However, the sampling bias does not account for differences between datasets when compared on a profile-by-profile bases. ODCOD's 5 km optical depth has a median uncertainty of 0.12 ± 0.05 ($76\% \pm 40\%$ relative) that increases as optical depth becomes small. The most significant source of uncertainty in the ODCOD retrieval is wind speed. Through an AMSR-derived wind speed correction applied to the MERRA-2 winds, the ODCOD algorithm attempts to reduce wind speed biases in the retrieval. Further sources of uncertainty are the surface return

Moved up [17]: 2012) and MODIS (Holz et al.,

Deleted: 2016) and thus can be used confidently. While ODCOD also provide column optical depth estimate when transparent water clouds are present, a large effort remains to quantify potential artifacts introduced into the surface returns by the non-ideal transient response of the photomultipliers and to understand the multiple scattering effects of water clouds on ODCOD and the significance of their impact on the reported cloud optical depths.¶

Deleted: Depth (ODCOD) algorithm. Accurate estimates of the ocean surface integrated attenuated backscatter (IAB) are obtained by fitting a model of CALIOP's expected ocean surface return shape to the 532 nm surface return measurements. Particulate two-way transmittances, from which optical depths are derived, are retrieved by scaling the estimated IAB to an unattenuated modeled surface reflectance that has been corrected for molecular and ozone two-way transmittances. ODCOD total column optical depth estimates are derived for the entire CALIPSO data record wherever qualified ocean surface detections are made.¶

¶

Deleted: ODCOD retrievals in the daytime were compared to 10 collocated airborne HSRL underflights, 3 years of MODIS AODs interpolated to 532 nm and the ODCOD retrieval location, and 3 years of collocated SODA 333m retrievals. The median daytime differences found were -0.037 ± 0.052 , with ODCOD lower than HSRL; -0.010 ± 0.041 , ODCOD lower than MODIS; and 0.004 ± 0.035 , ODCOD higher than SODA. Correlation coefficients were found to be 0.775, 0.834, and 0.887 respectively. Nighttime retrievals of 11 HSRL underflights and 3 years of SODA data showed median differences of 0.021 ± 0.032 and 0.027 ± 0.034 , both with ODCOD higher and correlation coefficients of 0.721 and 0.891 respectively. However, the expected sampling bias between daytime and nighttime data, inherent in all CALIOP-based surface return optical depth estimates and seen in ODCOD, is not found in (... [58])

model, the surface return model parameters, the surface retro reflectance model, noise in the lidar surface return, the lidar calibration coefficients, and the lidar gain coefficients. A better reflectivity model that accurately characterizes phytoplankton, salinity, temperature, and other factors might improve the retrieval, as could a more accurate impulse response model.

Unlike CALIOP's standard optical depth estimates, ODCOD does not suffer from missing optical depth due to undetected layers, because the light from the lidar is attenuated by the entire column before reaching the ocean surface. Therefore, all attenuation in the column is accounted for in the ODCOD optical depth estimate. ODCOD provides an internally consistent constraint for deriving extinction profiles that, on average, may be improved over the standard CALIOP profiles (Burton et al., 2010; Painemal et al., 2019; Li et al., 2021). ODCOD AOD retrievals are also being assessed for estimating regional layer-averaged lidar ratios for CALIOP by the Models, In situ, and Remote sensing of Aerosols (MIRA) group (Trepte et al., 2023). Because ODCOD is a single instrument technique that is available for the entire CALIPSO mission, ODCOD's total column optical depth estimates provide unique opportunities for analysis and improvements for the CALIPSO mission and more.

The surface integrated attenuated backscatter (IAB) is traditionally computed from a numerical integration of the samples proximal to the surface. Call $x(t)$ the impulse response function (IRF). Assume that the sampling of this function satisfies the Nyquist-Shannon sampling criteria, i.e., that the sample rate is at least twice the maximum analog bandwidth of the signal. In this case, the IRF signal can be recovered exactly and expressed as follows.¶
$$x(t) = \sum_{n=-\infty}^{\infty} x(nT) \operatorname{sinc}\left(\frac{t-nT}{T}\right)$$
- Formatted:** Normal

Bit Number	Short Name	Description
0	Time delay shifted	Of the measurements provided to the ODCOD algorithm by the surface detection algorithm, ODCOD adjusted the JRM such that the first data point of the surface detection data was not the first point on the JRM
1	Surface has too many points	The surface detection algorithm provided surface measurements covering a range greater than 120 m
2	Surface point added to beginning	The ODCOD algorithm added measurements above the surface data provided by the surface detection algorithm
3	Surface point added to end	The ODCOD algorithm added measurements below the surface data provided by the surface detection algorithm
4	Surface data missing first point	When solving for the alignment of the JRM , the first measurement that should fall on the JRM curve was not originally provided by the surface detection algorithm
5	JRM Shifted	ODCOD had to adjust the JRM such that the first measurement provided by the surface detection algorithm was not the first point on the JRM
6-9	Unused	unused
10	No surface detected	The surface detection algorithm did not find a surface
11	The surface is not ocean	The International Geosphere–Biosphere Programme (IGBP) surface type is not 17 for ocean
12	Surface is sea ice	The depolarization ratio of the surface is greater than 0.15
13	Wind speed is invalid	The Corrected MERRA-2 wind speed is outside of the inclusive range 0.025 m s ⁻¹ to 43 m s ⁻¹
14	Time delay cannot be found	ODCOD has failed to find the time delay of the JRM from the surface measurements provided by the surface detection algorithm
15	Too few measurements	The surface detection algorithm failed to provide enough measurements to solve for the time delay
16	Area too large	When solving for the JRM area, the solution grew unrealistically large
17	Scale factor failed	While attempting to solve for the scale factor, a failure occurred
18	Surface saturation	Surface saturation was detected in the surface return
19	Negative signal anomaly	Negative signal anomaly was detected in the surface return
20	Surface had no valid data	The surface detection algorithm provided no valid data for the surface measurements
21	Bad input data	Can be caused by several conditions related to input data being fill values or invalid
22	Averaged surface not found by derivative method	The surface detection algorithm had to resort to an alternative method of finding the surface when the surface return was averaged to coarser resolutions that may not be reliable for ODCOD
